1. Thermoplastic Polyolefin Elastomers

Traz Ouhadi and Sabet Abdou-Sabet

1.1. Introduction and Definition

The significant growth of thermoplastic elastomers in the marketplace since the 1970s can be attributed to the family of thermoplastic polyolefin elastomers because of the wide range of products available, their favorable price – performance relationship, and their acceptance by the automotive industry. Historically, Uniroyal Chemical Company was the first company in 1972 to introduce a thermoplastic polyolefin elastomer to the market.

In 1971, W. K. FISHER [1], [2] filed patent applications on thermoplastic elastomer (TPE) blends based on rubbers that are copolymers of monolefinic monomers — such as ethylene – propene copolymer (EPM) or ethylene – propene – diene terpolymer (EPDM) (⟶ Rubber, 3. Synthetic) — with crystalline polyolefin resin, e.g., polypropylene (PP). FISHER employed partial vulcanization of the rubber component to maintain the thermoplastic processibility of the blend by limiting the amount of peroxide. Cross-linking was performed while mixing under dynamic shear, a process known as dynamic vulcanization. However, the dynamic vulcanization process and the first EPM – PP blend were discovered independently by GESSLER et al. [3] (Exxon) and HOLZER et al. [4] (Hercules) in 1958 and 1961, respectively. Two types of thermoplastic rubber (TPR) were produced. One type consisted of simple blends of EPDM and PP; the other contained *partially vulcanized rubber* in the blend. In 1972 – 1976, most major EPDM producers commercialized products based on simple blends. In general, the TPR products were elastomeric according to DIN 7724 and ISO 1382–1982 definitions, yet these products were not seriously considered for true rubber replacement applications.

Significant improvement in the properties of these blends was achieved in 1975 by CORAN et al. [5] by *fully vulcanizing the rubber phase* under dynamic shear without affecting the thermoplasticity of the blend. This discovery was advanced by ABDOU-SABET et al. [6] in 1977 by the use of phenolic curatives to achieve further improvement in rubber-like properties and processing characteristics.

Therefore, the field of thermoplastic elastomers based on polyolefin rubber – plastic blends grew along two distinctly different product lines or classes: one class consists of a simple blend of α-olefin rubber in a crystalline polyolefin resin and classically meets the definition of thermoplastic polyolefin (TPO). In the production of the other class, the rubber component in the TPO is subjected to dynamic vulcanization to generate a TPE with true rubber-like properties. This class is called thermoplastic vulcanizates (TPVs) or dynamically vulcanized alloys (DVAs).

These two classes of materials share a common basic composition. The plastic phase is a semicrystalline polyolefin such as isotactic and syndiotactic polypropylene, propene copolymer, high-density polyethylene, low-density polyethylene, linear low-density polyethylene, ethylene – vinyl acetate copolymer, ethylene – methacrylate copolymer, or ethylene – ethyl acrylate copolymer. The rubber phase may consist of EPM, EPDM, isobutene – isoprene copolymer (butyl rubber), halobutyl rubber, isobutene – *p*-methylstyrene copolymers, halogenated isobutene – *p*-methylstyrene copolymers, natural rubber, styrene – butadiene copolymers, nitrile – butadiene copolymers, styrene – isoprene – styrene block copolymers and their hydrogenated version, etc. (For a description of component polymers, see ⟶ Polyolefins; see ⟶ Rubber, 3. Synthetic).

1.2. Thermoplastic Polyolefin Blends

Thermoplastic polyolefin compositions based on the blends of a polyolefin rubber and a semicrystalline polyolefin have increased dramatically in popularity in recent years. The first thermoplastic polyolefins blends commonly referred to as TPOs were *mechanical blends* of polyolefin polymers. The most common types of TPO are composed of polypropylene and ethylene – propene rubber (EPR). In principle there are a wide variety of starting materials, an almost unlimited number of formulations for this type of TPOs in major part custom-tailored to meet the varied requirements of the most demanding low temperature high impact applications.

In addition to these mechanical blends, advances in Ziegler – Natta catalysis and reactor design have allowed the preparation of such blends in the polymerization reactor from ethylene and propene monomers. These are commonly called *reactor thermoplastic polyolefins* (RTPO). The amount of EPR content in RTPO can be varied from less than 15 wt %, which is most common, to around 70 wt %. Commercial demand for TPO and RTPO has been particularly strong in the automobile bumper application, especially in Europe and Japan. Such dominance has overshadowed the opportunities for TPO in other market sectors. Advanced compounding technology is being used to generate TPO compounds specific to the application; such technology can also be applied to RTPO.

Mechanically prepared blends are produced by using either batch or continuous mixing techniques. The most common batch mixers are internal intensive mixers, such as the Banbury. Continuous mixing techniques can be performed in either single- or twin-screw extruders. Mixing procedures can be extremely varied because of the wide range of TPO recipes in use, as well as the mechanical characteristics of individual process lines.

Reactor thermoplastic polyolefins are the newest variety of TPO. The amount of rubber (generally EPR) that may be included in a reactor-generated TPO is strongly dependent on the catalyst and process used. The development of a new generation of Ziegler – Natta catalysts (4th generation) with long-lived activity and the capacity of providing PP particles with very high porosity permit the polymerization of a high-rubber component (up to 70 wt %) (soft component) inside a shell or skin of crystalline PP. This has been accomplished by the *Cataloy process* [7], which is based on a three-stage reactor. The first stage consists of a tubular loop reactor that produces semicrystalline polypropylene. In the second and third reactors, ethylene and other olefinic monomers are introduced, and ethylene copolymerizes with propene to form the ethylene – propene copolymer rubber inside the semicrystalline homopolymer PP produced in the first reactor; this minimizes reactor fouling. The formation of a continually growing polymer skin and porous particle provides a reaction bed within which the copolymer is produced. This advanced technology in Ziegler – Natta catalysis has been referred to as *Reactor Granules Technology* [8] because the growing polymer particle itself has become the polymerization reactor.

1.2.1. *Morphology*

Thermoplastic polyolefins possess primarily a two-phase morphology. At least one phase — the thermoplastic component of the blend — is continuous. The second, or rubber, phase can be either co- continuous or dispersed, depending on the composition of the blend. The mixing conditions, surface energy, viscosity, and molecular masses of the two polymers determine at what polymer ratio the two phases are co- continuous [9], [10], since at extreme concentrations (i.e., a 10 : 90 or 90 : 10 ratio) the minor component is expected to be the dispersed phase.

ONOGI and coworkers [11], [12] reported phase inversion in the blends of crystalline polypropylene with EPR or EPDM elastomers when the polypropylene content reaches 50 to 60 %.

LOHSE [13] describes the morphology of the simple blend as unstable because the polymers are not miscible, especially at a 50 : 50 polymer ratio. The rubber phase, particularly when present as the dispersed phase, tends to agglomerate or coalesce. Such phase growth is undesirable and would lead to changes in properties and performance as a function of mixing and processing. To stabilize against phase growth, additives or *compatibilizers* are usually added. The preferred compatibilizer is a graft or block copolymer of isotactic PP and EPR. One approach has been described in [14]. The compatibilizer is generated from EPDM containing vinylnorbornene as the diene; the pendant double bond is then used to graft to the PP. The addition of 3 % of a compatibilizer to the blend improves adhesion between the phases and leads to finer dispersion of the phases. This is demonstrated by the smaller size of the rubber phase and the considerably decreased phase growth (Fig. 1).

Figure 1. Morphology of EPDM – PP thermoplastic polyolefins containing 0 and 3 mol % compatibilizer

1.2.2. *Elastomer Component, Soft Domain*

Either ethylene – propene or ethylene – propene – diene rubber is suitable for these blends. The double bonds in the EPDM are not used as chemically active sites for curing. However, they provide considerably wider choices in raw material selection and undoubtedly affect the green strength properties of the elastomer by changing the number of branch points in the rubber molecule. The diene most commonly used in the EPDM is ethylidene norbornene (ENB), but 1-4 hexadiene

(1,4 HD), dicyclopentadiene (DCPD), or vinylnorbornene (VNB) may be used.

EPR rubbers contain 45 – 85 mol % ethylene, 55 – 15 mol % propene, and 0 – 10 mol % diene. EPDM with an ethylene content > 75 mol % exhibits crystallinity that can be examined by differential scanning calorimetry or ^{13}C NMR by measuring the ethylene sequence index [15]. The net effect of ethylene crystallinity is that it greatly strengthens the rubber and, consequently, the blend.

1.2.3. *Plastic Component, Hard Domain*

In most commercial TPO, the hard domain is isotactic polypropylene homopolymer or a copolymer (random or block) with a small amount of ethylene as comonomer for random PP and until 25 mol % ethylene for block copolymer PP. These resins are semicrystalline. The homopolymer has an *mp* of 155 – 165 °C, while the random copolymer has an *mp* of 140 – 155 °C. Ethylene decreases the rigidity of the polymer and improves the low-temperature properties at a sacrifice of the upper performance temperature.

1.2.4. *Compounds, Trade Names*

The two main components of a TPO blend are ethylene – propene rubber and polypropylene. Additional materials, such as other elastomers, processing oils, antioxidants, reinforcing and nonreinforcing fillers, colorants, and other additives to enhance the adhesion or the paintability of the product, are often used. Typical TPO compounds and their properties are listed in Table 1, and the suppliers and trade names of such materials are listed in Table 2.

Table 1. Typical TPO compositions and properties

Components, properties	TPO type		
	1	2	3
EPDM, parts by weight	20	57	85
PP, parts by weight	80	43	15
$CaCO_3$, parts by weight	60	8	8

Vyflex	Lavergne	North America
Novalast	Nova Polymers Inc.	North America
Elastamax	PolyOne	North America
Salflex	ABC Group	North America
J-Prene	J-Von	North America
Tamfer	Mitsui	Asia
Thermoran	Mitsubishi/JSR	Asia
P.E.R.	Tokoyama Soda	Asia

Automotive and electrical applications are the major markets for TPO. Automotive constitutes by far the largest market because of the excellent weatherability and low cost of TPOs. Some examples are bumper covers, interior trim, fender extensions, etc.

TPOs have good electrical properties in combination with good ozone resistance, which makes these materials a good choice for low voltage wire and cable applications where hot tension set at 200 °C is not a requirement. Such applications can be found in automotive booster cable, flexible cord, and welding cable insulation.

1.2.5. *Processing*

TPOs can be processed on most common thermoplastic equipment. Products can be formed by injection molding, extrusion, vacuum forming, injection blow molding, extrusion blow molding and so on. The versatility of the compounding TPO products permits designing of compounds to fit the available process and equipment.

1.3. Thermoplastic Vulcanizates

Thermoplastic vulcanizates made via a dynamic vulcanization (TPV) are rubbery engineered polymers blends with fabrication characteristics of a conventional thermoplastic and perform the properties of a conventional thermoset rubber.

TPVs offer a variety of practical advantages over conventional thermoset rubbers. These advantages are:

1. Little or no compounding or blending. Most TPVs are fully formulated and ready for use.
2. Simpler processing with a fewer steps. TPVs have the processing simplicity of thermoplastic.
3. Shorter fabrication cycle time and consequently higher productivity for fabrication parts.
4. Recycling of scrap material (regrind). After each step, the scrap from thermoset rubber should be discarded while with TPVs all the eventual scrap is reground and used as virgin material.
5. Lower energy consumption
6. Better quality control and closer tolerances on finished articles
7. In most cases a density lower than a comparable thermoset rubber.

1.3.1. *Dynamic Vulcanization*

Dynamic vulcanization was discovered by GESSLER et al. [3]. In an attempt to improve the impact properties of PP they partially vulcanized halobutyl rubber in a polypropylene matrix under continuous mixing. Dynamic curing generates the same necessary cross-links or three-dimensional polymer structures as static curing. In dynamic curing, however, these structures are generated in small rubber particles dispersed in the uncross-linked thermoplastic polymer matrix as a microgel. The formation of such dispersed-phase morphology depends on establishing a high degree of cure (CORAN et al. [5]). The rubber phase is fully vulcanized in a plastic matrix (thermoplastic vulcanizate). The rubber particles are in the order of 1 – 2 µm in size. Fully curing the rubber phase has led to significant improvement in the material properties including

1. Higher ultimate tensile strength
2. Lower tension and compression set
3. Better property retention at elevated temperature
4. Greater resistance to attack and swelling by fluids
5. Greater flexural fatigue resistance
6. More consistent processibility

Partially cross-linked blends give modest improvement [1], [2].

The effect of the size of the rubber particles and the degree of cure on material properties can be seen in Figures 2 and 3. By proper choice of the curatives, S. ABDOU-SABET et al. [6] demonstrated that rubber-like properties can be improved beyond those achieved by CORAN. Improvements in compression set, oil resistance, and the processing characteristics of the material were achieved by applying phenolic curatives (e.g., dimethyloloctylphenol). These improvements are beyond those expected from the state of cure. They probably are due to in situ formation of a graft copolymer between EPDM and PP that optimizes the interfacial adhesion between the rubber particle and the polypropylene matrix, thus allowing for better elastomeric properties. The graft copolymer could have been generated through the functionalization of PP with dimethyloloctylphenol, which then reacts with EPDM [16].

Figure 2. Effect of particle size on stress – strain relationship

Figure 3. Effect of the degree of cure on mechanical properties

a) Percentage of swell in ASTM oil no. 3; b) Tensile strength at 100 °C; c) Tensile strength at room temperature

More importantly, significant improvement in processing was achieved over that obtained with the sulfur cure, as shown in Table 3. The use of dimethyloloctylphenol as curative allowed the generation of very soft TPV (as soft as 35 Shore A, with compression set approaching that of a thermoset rubber) while maintaining excellent thermoplastic processing. The poor processing characteristics of sulfur- cured TPV are due to phase growth of the dispersed rubber particles. The polysulfidic bonds generated during vulcanization undergo sulfur exchange reactions leading to significant coalescing of the rubber particles.

Table 3. Effect of cross-linking agent on properties of EPDM rubber – PP TPV

	Cross-linking agent			
Property	**None**	**Sulfur**	**Dimethylolalkylphenol**	**Peroxide**
Hardness Shore D	36	43	44	39
T.S.,[a] MPa	4.96	24.3	25.6	15.9

Processing characteristics[e]	+	–	+++	+

[a] T.S. = tensile strength.
[b] M_{100} = modulus at 100 % elongation.
[c] U.E. = ultimate elongation.
[d] Comp. set = compression set.
[e] + = good; – = poor; +++ = excellent.

Other vulcanization systems are used to cure the rubber phase of TPV. Peroxide with an adequate coagent is the most common curing system after phenolic curatives. The role of coagent is to enhance the cross-linking efficiency for the rubber phase. Apart from cross-linking efficiency, the use of a coagent can also affect the molecular structure of the cross-links. The most common type of coagents are polyfunctional organic molecules.

Another effective vulcanization system reported in several patents [17], [18] uses a hydrosilylation agent with platinum containing catalysts. This cross-linking system works with rubber containing diene groups, preferably with sterically unhindered carbon-carbon double bond.

A new cross-linking system to make TPV based on hydrolyzable organosilane grafted rubber molecules is reported in [19-21]. The organosilane function is hydrolyzed during the dynamic mixing of rubber with the thermoplastic phase (PP) followed by condensation reaction with help of an organotin derivative catalyst such as dibutyltin dilaurate.

1.3.2. *Production and Morphology*

Melt mixing of the two polymers prior to dynamic vulcanization is the first requirement for a good TPV. The phase morphology of the uncross-linked blend will be influenced by the same variables discussed for TPO. S. ABDOU-SABET et al. [10] demonstrated for an 80 : 20 EPDM – PP blend that PP is the dispersed phase in an EPDM matrix. During dynamic vulcanization of such a blend, EPDM and PP have to undergo a phase inversion to maintain the thermoplasticity of the blend. In the initial stages of dynamic curing, two co- continuous phases are generated, and as the degree of cross-linking

increases during mixing, the continuous rubber phase becomes increasingly elongated and then breaks up into polymer droplets. As these droplets form, PP becomes the continuous phase. This can be seen in the SEM electron micrograph (Fig. 4), in which the EPDM phase appears white and the PP phase is black. Photograph 4 B shows that both phases are co- continuous. Figure 5. shows a TEM electron micrograph of a very soft TPV where EPDM phase appears in black and PP in white color.

Figure 4. SEM-Electron micrograph of an 80 : 20 EPDM – PP thermoplastic vulcanizate

A) Unvulcanized blend; B) Partially vulcanized; C) Fully vulcanized; D) Fully vulcanized and diluted to 20 : 80 EPDM – PP

Figure 5. TEM-Electron micrograph of a very soft TPV based on EPDM/PP

Reactor TPO can also be used as a raw material to make a TPV [22]. Reactor TPO, however, is not yet commercially produced with a diene function or other functionality in the rubber molecules. Therefore, cross-linking of the rubber phase can be performed only with peroxide. Peroxide curing is carried out while the necessary precautions are taken to protect polypropylene from chain scission and unzipping by the peroxy radical. Protection can be achieved via the incorporation of compounds in the blend that preferentially undergo reaction with the peroxides without affecting PP [23]. Such compounds include polyisobutylene, polybutadiene, and polybutene. Even then, achieving full cure is quite difficult, and only partial curing of the rubber phase is usually accomplished.

To achieve the best improvement in properties of TPV, certain conditions must be satisfied:

1. The higher the crystallinity of the plastic component, the better are the mechanical and elastomeric properties
2. The smaller the difference in critical surface tension between the rubber and the plastic, the smaller is the size of the dispersed rubber phase
3. The lower the entanglement spacing of the rubber chain, the better are the properties of TPV

1.3.3. *Types*

Theoretically it should be possible to make a large number of different classes of TPV by combination of at least one type of rubber with one type of thermoplastic. But practically, there is a limitation in the number of commercial TPV families due to limited number of compatible rubber-thermoplastic pairs. Obviously by use of adequate compatibilizing agent between a given rubber and a given thermoplastic, it is possible to expand the number of TPV families.

The discussion in this section is limited to those containing at least one polyolefin polymer.

EP/EPDM rubber -polypropylene based TPVs are the most common types of TPV [24]. The EP/EPDM-PP pair is the most used rubber (except for tire application) and thermoplastic material due to the excellent rubbery properties, heat and weathering resistance of EP/EPDM rubber and the excellent versatility, chemical resistance and inertness, and mechanical properties of PP. A broad range of vulcanization systems can be used as mentioned earlier to cross-link EPDM while only peroxide system can be used as cross-linking agent for EP rubber.

Natural rubber (NR) - polyolefin based TPVs [25] have been thoroughly investigated in an attempt to develop commercial products that take advantage of the attributes of natural rubber. Most of the research work was focused on *polypropylene-based material*. These NR – PP TPV thermoplastic natural rubbers (TPNRs) exhibited significant disadvantages compared to their EPDM counterparts and were not acceptable. Drawbacks stemmed from the poor thermal stability and the generation of excessive odor from the natural rubber component on processing at higher temperature. Again, partially cross-linked products exhibited co- continuous morphology, while those cross-linked to 95 % or higher of the natural rubber phase showed dispersed-phase morphology. Properties of this type of TPV are listed in Table 4.

Table 4. Typical properties of thermoplastic natural rubbers

Property	Rubber type				
	1	2	3	4	5
Shore A hardness	50	60	70	80	90
	3.1	4.1	5.3	6.3	8.2

M_{100},[a] MPa

[a] M_{100} = modulus at 100 % elongation.
[b] T.S. = tensile strength.
[c] U.E. = ultimate elongation.
[d] Comp. set = compression set.

Natural rubber – polyethylene-based compositions [26] have also been studied extensively. These TPVs should possess good low-temperature flexibility and elastic recovery for low-temperature applications.

Butyl rubber-polypropylene based TPVs are another family of TPVs where a butyl or halobutyl rubber is used as elastomer componen. In 1988, R. C. PUYDAK et al. [27] introduced *butyl rubber-based TPV* for applications requiring impermeability to oxygen and water vapor transmission. Such products are useful in sports bladders and blood vial stoppers.

Polymers with significantly different critical surface tension [28] can still be mixed together with the help of a compatibilizer to improve wetting characteristics or interfacial adhesion [29] between the two phases, thus allowing for the generation of preferred morphology prior to dynamic vulcanization. The application of compatibilization technology allowed the mixing of polar rubbers (e.g., *nitrile rubber* [30], [31] and *acrylate rubber* [32]) with polypropylene, followed by dynamic vulcanization to improve the properties as much as possible. Figure 6 illustrates the effect of the compatibilizer (maleated polypropylene) on polypropylene – ethylene – acrylate rubber TPV.

Figure 6. Effect of compatibilizer (maleated polypropylene) on ultimate tensile strength of polypropylene – ethylene – acrylate rubber TPV

Only a small amount of compatibilizer is needed for compatibilization. The function of the compatibilizer is analogous to that of a surfactant that emulsifies and stabilizes a water – oil mixture. Effective compatibilizers are generated by forming a graft or block copolymer; the structures of the blocks must be similar to the phases to be compatibilized. In that case, one block of the copolymer is soluble in the polyolefin resin, while the other is soluble in the polar rubber phase. Graft formation must be controlled to achieve the desired interfacial adhesion while preserving a dispersed phase morphology. Generation of primary chemical bonds between the two phases could lead to an interpenetrating network morphology. Such networks could result in thermoset characteristics and the loss of the thermoplastic processing advantage.

1.3.4. *Processing*

Thermoplastic vulcanizates or block copolymers that are made of soft and hard blocks are processed or fabricated by the same techniques normally used for rigid plastics. This enables the fabrication of elastomeric articles with improved efficiency and economy over those of a conventional thermoset rubber. Scrap from TPV can be recycled readily, whereas thermoset rubber scrap is generally discarded, resulting in a sizeable cost penalty. The thermoplastic nature of TPV enables fabrication by methods unavailable to thermoset rubbers. These include blow molding, thermoforming, and heat welding. Thermoplastic vulcanizates have extremely non-Newtonian flow properties, and their viscosity is highly sensitive to shear [33]. At low shear rates, they flow very poorly; at high shear rates, however, they are quite fluid, enabling rapid injection molding cycles.

1.3.5. *Performance and Product Positioning*

ASTM D-2000 attempts to classify rubber products according to their performances in dry heat (dry heat service temperature) and ASTM oil no. 3 (see also ⟶ Rubber, 3. Synthetic). Conventional thermoset rubber occupies certain regions on a performance chart. Such classification is, however, insufficient because other characteristics such as

dynamic properties, stress relaxation, barrier properties, UV resistance, adhesion, and colorability, also play an important role in material selection. Nevertheless, according to the ASTM D-2000 classification, EPDM – PP TPVs have performance characteristics superior to chloroprene (Neoprene) rubber. The properties of TPO, however, are considerably less elastomeric, and TPOs occupy a lower-performance category (Fig. 7).

Figure 7. Classification of elastomers according to heat and oil performance

*AEM = ethyl acrylate – ethylene copolymer; CM = chlorinated polyethylene; CSM = chlorosulfonated polyethylene; HNBR = hydrogenated acrylonitrile – butadiene rubber; SBR = styrene – butadiene rubber; Geolast, Santoprene, Trefsin, Vistaflex, and Viram-6000 are registered trade names of commercial TPVs (see Table 5)

1.3.6. *Uses*

Since their introduction in 1981, TPVs have found thousands of commercial uses worldwide. Generally speaking, these materials have been used in most rubber applications with the exception of tires. Thermoplastic vulcanizates are employed, e.g., in automotive and construction applications, in foods, hardware, appliances, business machines, mechanical rubber goods, and sporting goods, as well as electrical and medical applications. The uses can vary from the syringe stoppers in medical syringes to the rack-and-pinion boots on the steering mechanism of a front-wheel-drive automobile.

1.3.7. *Commercial Products and Trade Names*

Advanced Elastomer Systems who commercialized the first TPV (Santoprene) in 1981, is leading the market for this family of products. Global market demand for TPVS is forecast to increase 8 to 10 % per year. The strong gain anticipated for TPVs results from an intense product development activity led by Advanced Elastomer Systems. Currently, a number of products are on the market (see Table 5). Only fully vulcanized materials achieve the full benefit of dynamic vulcanization.

Table 5. Suppliers of thermoplastic vulcanizates

Trade name	Supplier	Polymer type	Degree of cure
Santoprene [a]	AES	EPDM – PP	full
Trefsin [b]	AES	butyl-PP	full
Dytron [c]	AES	EPDM – PE	full
Sarlink 3000	DSM	EPDM – PP	partial
Sarlink 2000	DSM	butyl – PP	partial
Hifax-XL	Himont	EPR – PP	partial
Vyram [d] 9000	AES	EPDM – PP	partial
Vyram [d] 6000	AES	natural rubber – PP	full
Milastomer	Mitsui	EPDM – PP	partial
Sumitomo TPE	Sumitomo	EPDM – PP	partial

Hans-Georg Wussow

2.1. Introduction

Thermoplastic polyurethanes (TPUs) are a group of elastic materials whose common structural feature is the urethane group –O–CO–NH– arising from the reaction between diisocyanates and long- and short- chain diols. The long- chain polyester or polyether diols form flexible soft segments in the temperature range of use, while the short- chain diols and diisocyanates form rigid or hard segments. Since soft and hard segments are arranged alternately along the molecular chain, TPUs belong to the $[AB]_n$-type block copolymers. Intermolecular interactions between the hard segments lead to the formation of glassy or paracrystalline hard domains, which, as physical cross-linking points, can be reversibly melted during thermoplastic processing. Variation in the ratios of soft and hard segments and monomers permits the production of materials in the modulus range of ca. 5 – 700 MPa, corresponding to ca. 60 Shore A to 70 Shore D. Because of their very good mechanical properties, especially extraordinary resistance to abrasion, the great choice of monomers available for the production of “tailor-made materials”, and efficient thermoplastic processibility, TPUs have found a wide range of applications since their introduction to the market at the beginning of the 1960s. Further information on the production and properties of TPUs can be found in [34-37].

2.2. Raw Materials (⟶ Isocyanates, Organic; ⟶ Polyesters; ⟶ Polyoxyalkylenes)

The raw materials used in TPUs are diisocyanates, short- chain diols with molecular masses of 61 – ca. 600, and long- chain polyester and polyether diols with average molecular masses between 600 and 4000, so- called polyols.

Diisocyanates. 4,4′-Diisocyanatodiphenylmethane (4,4′-methylenediphenyl diisocyanate, MDI) [101-68-8] is industrially by far the most important diisocyanate. It can be used to produce materials that offer the most favorable compromise between price, thermoplastic processibility, and mechanical properties. Other *aromatic diisocyanates* used are 3,3′-dimethyl-4,4′-biphenyl diisocyanate (3,3′-tolidene-4,4′-diisocyanate, TODI) [38] and 1,4-phenylene-diisocyanate (PPDI) [104-49-4] [39]. Among the *aliphatic diisocyanates* the following are important: 4,4′-dicyclohexylmethane diisocyanate (H_{12}-MDI) [5124-30-1] (as the isomeric mixture) [40] and 1,6-diisocyanatohexane (hexamethylene diisocyanate, HDI) [822-06-0]. The aliphatic diisocyanates are much less reactive toward alcohols than MDI [41].

Short-Chain Diols. The most important short- chain diol used as a chain extender is 1,4-butanediol. For TPUs with improved dimensional stability at elevated temperature, 1,4-bis(2-hydroxyethoxy)benzene [hydroquinone bis(2-hydroxyethyl) ether] [104-38-1] is also used. The use of diol mixtures (e.g., with ethanediol or 1,6-hexanediol) gives products with a broader processing range [42].

Polyols.
Polyester Polyols. The most important polyols are polyadipates of short- chain diols with two to ten carbon atoms. Butanediol, hexanediol, ethanediol, and mixtures of these diols are most commonly used. The resistance to hydrolysis of the polyol and TPU increases as the molecular mass of the diol increases. Polycaprolactones and polycarbonate diols with their good to excellent resistance to hydrolysis are also employed. The most widely used products have average molecular masses of 1000 – 2000. As polycondensation products, polyadipates have a broad molecular mass distribution [43]. They frequently contain unreactive ring esters formed as byproducts. For TPU production the acid number of the ester polyols should be as low as possible, preferably < 1 mg KOH/g, because carboxyl groups react with isocyanates and impair the resistance to hydrolysis.

Polyether Polyols (⟶ Polyoxyalkylenes). Poly(tetramethylene oxides) are the most important polyether polyols for the production of TPUs. Poly(propylene oxides) [poly(propylene glycols)] and copolymers with ethylene oxide give products with poorer properties; normally, they are used together with polyester polyols. The molecular mass distribution of the polyether polyols follows the Poisson distribution and is thus considerably narrower than that of the corresponding polyesters. Poly(propylene oxides) have predominantly secondary hydroxyl groups as terminal units and are therefore considerably less reactive than other polyols.

Additives. Internal release agents, such as esters of montanic acid (octacosanoic acid), silicones, or amide waxes in quantities up to 2 %, are used as *processing aids*. TPUs based on polyesters can be protected effectively against *hydrolytic degradation* by the addition of carbodiimides [44]. Protection against *microbial degradation,* for example on prolonged contact with soil, is also possible. Sterically hindered phenols and amines are used as *antioxidants,* mainly to protect against discoloration and degradation, particularly in the case of polyether TPUs at the high production and processing temperatures often required. Yellowing because of the effect of light can be slowed considerably through the use of *light stabilizers* such as benzophenones sterically hindered amines (HALS) or benzotriazoles [45].

Plasticizers are used only to achieve hardness levels below ca. 70 Shore A [46-48]. Short glass fibers are used mainly to *reinforce* TPUs. Many additives, such as colorants, antiblocking agents, antistatic agents, and flame retardants, are supplied as concentrates.

2.3. Production

General. The industrial production of TPUs is carried out virtually exclusively in continuous, solvent-free processes [49]. According to Flory statistics [43] the required high molecular masses are achieved only at high conversions and an essentially stoichiometric ratio of NCO and OH groups. At an NCO : OH ratio < ca. 0.97, products with the required properties are generally not obtained [50]. Too high an excess of NCO can lead to cross-linking through allophanate and biuret formation even after long periods [51]. A prerequisite for maintaining exact stoichiometric ratios is the use of raw materials that are as pure — especially anhydrous — as possible and of exact metering devices. Prepolymer and one-shot processes can be used to carry out the reaction (⟶ Polyurethanes, ⟶ Polyurethanes – Reactive One-Pack Systems). In the one-shot process, OH- and NCO-functional reactants are mixed with each other in one step. In the prepolymer process, a prepolymer with terminal NCO groups is first formed from a long- chain polyol and diisocyanate. This prepolymer is then mixed with the chain extender. Reactivity differences (e.g., between polyether polyols and butanediol) can be overcome with this process. The process used affects the segment length distribution and thus the morphology of the final product [52], [53].

Belt Process [54]. Liquefied raw materials are mixed continuously in a mixing head and poured onto a continuous belt, which passes through an oven heated to ca. 70 – 130 °C, where the reaction proceeds further. The congealed product is ground to irregular pellets. It can be melted in extruders, possibly along with additives, and formed into regular pellets. According to a modification of this process [55] the reaction is carried out to a desired degree of conversion, generally > 80 %, on the belt, and the congealed mixture is then fed immediately into an extruder where the reaction is continued and the mixture is homogenized. Finally, the polymer is pelletized. In the belt process the temperature and residence times in the heated zone can be adapted to the requirements of the particular product.

Reaction Extruder Process. A twin-screw extruder serves as the reactor [56-59]. The screws are conrotating and can be set to the required shearing ratios by a combination of kneading and transporting parts. Temperature is controlled by using barrel sections that can be heated separately. The reactants and additives can be charged at different locations. In this way a continuous prepolymer or one-shot process is possible without additional equipment. The bulk temperatures are generally > 200 °C. The product is extruded continuously and pelletized immediately after the head or after passage through a cooling area. As in the belt process, subsequent sieving and drying processes occur. In the reaction extruder process, finished pellets can be obtained from starting materials with the addition of all additives (including glass fiber or

other thermoplastics) in one process step [60].

Comparison of Products. Because of different shearing and temperature conditions, the type of process used significantly affects the morphology and thus the processing properties of the products. Starting from identical raw materials more opaque products are formed in the belt process with larger hard segment domains that melt at higher temperature, whereas the reaction extruder process gives more transparent, lower-melting products.

2.4. Properties

Morphology [37], [61], [62]. The physical properties of TPUs are determined by their polyphase structure consisting of soft segments with very low glass transition temperatures, hard segments with high melting ranges, and mixed phases. This structure arises from the incompatibility of the hard and soft segments, which, on cooling from the melt during production and processing, leads to partial or complete separation of the phases that are bonded covalently with each other. The extent of separation and the phase structure are determined mainly by the stoichiometric composition of the polymer; the statistical distribution of the hard and soft segments [52]; the structure of the polyol [63], the diisocyanate and the chain extender, and the thermal history. The latter results from the kinetics of the separation and crystallization processes, and from the cleavage and transurethanization during production, processing, and possible tempering of the product [64-67]. In polyethers, phase segregation is more pronounced than in polyesters and increases as the molecular mass of the polyol increases. Many investigations of the structure [65], [68], [69] phase interactions [70], [71], [69] and structure – property relationships of TPUs have been carried out, mainly on model substances [72-74]. Macroscopically, the soft segments determine the elastic ductility, the low-temperature properties, and the basic chemical properties, while the hard segments are important for dimensional stability at high temperature and the processing properties.

Technical Properties. By varying the proportion of the hard segment the modulus of elasticity can be varied over a range of ca. 5 – 700 MPa without the use of plasticizers or reinforcing agents. Typical contents of the long chain diol range from 30–75 wt%. Products containing no [41] or only very small proportions of soft segments can no longer be regarded as thermoplastic elastomers [75]. Table 6 gives an overview of some properties of different types of product.

Table 6. Typical mechanical properties of TPUs with different hardness based on polyester polyols (example Desmopan, Bayer)

Property	Test standard (ISO)	Desmopan			
		385	345	359	372
Density, mg/m^3	1183	1.2	1.21	1.23	1.24
Hardness, Shore A/D	868	86 A	47 D	59 D	73 D
Tensile stress at break, MPa	527-1, -3	52	52	60	70
Elongation at break, %	527-1, -3	550	450	400	330
Tear resistance, kN/m	34-1	70	100	160	220
Flexural modulus, MPa	178		70	180	650
Abrasion loss, mm^3	4649	30	30	35	30
Compression set, %					
70 h/22 °C	815	30	25	30	
24 h/70 °C	815	55	42	60	

Figure 24 shows the dependence of tensile modulus on temperature for adipate-based TPU with different hardness; typical stress-strain diagrams are shown in Figure 25.

Figure 24. Tensile modulus of elasticity vs. temperature for polyadipate based TPU (example Desmopan, Bayer)

Figure 25. Stress-strain curves of polyadipate-based TPU with different hardness (example Desmopan, Bayer)

High extension with very low residual extension, high tensile and tear strength, high moduli of elasticity at a given Shore hardness, and excellent abrasion resistance are common to all TPUs. Polyester TPUs are superior to polyether products with regard to strength and resistance to oxidation or swelling by oils, fats, and water, while they are inferior with regard to

resistance to hydrolysis or microbial attack and impact resistance at low temperature. Hybrid types from polyester and polyether polyols combine the advantages of both types to a certain extent [76], [77].

Unstabilized TPUs based on MDI turn yellow through the action of light, initially without the impairment of mechanical properties. TPUs based on aliphatic diisocyanates do not show this discoloration. The lower temperatures of use are determined by the glass transition temperature of the soft phase (–20 to – 60 °C), and the upper ones by the onset of softening of the hard domains. Depending on the hardness, softening starts at ca. 80 – 100 °C (see ⟶ Polyurethanes). Hard products can be kept at up to ca. 120 °C for short periods. TPUs are soluble in polar, aprotic solvents such as *N,N*-dimethylformamide, methyl ethyl ketone, or *N*-methylpyrrolidone.

2.5. Processing and Use [34], [35], [78], [37], [81]

TPUs can be processed by all methods available for thermoplastics, such as injection molding, extrusion, blow molding, sintering, and calendering, although not all types are suited to every processing method. Melt temperatures range between 180 and 250°C, depending on hardness and other parameters. Typically, the melt viscosity of TPU is strongly temperature-sensitive ▪in which way? ▪. Generally only products with hardnesses up to ca. 50 Shore D can be extruded. Generally, extrusion becomes more and more difficult with increasing hardness above ca. 50 Shore D, due to formation of gel particles resulting from crystallization effects or side reactions.

TPUs are used in all those areas where their high strength and excellent resistance to abrasion, oil, and many other solvents are important. The large number of uses includes bases for shoe heels, soles and studs, or sports shoes, screens for the classification of minerals, rollers, tool parts, toothed belts, gaskets, electrical plugs, coupling elements, ear tags for animals, parts for car bodies, instrument panels, bearing shells, ski boots, seals, cable sheathings, tubing of all types, blown films, profiles, coatings, and medical equipment such as tubing and catheters. TPUs are also used for melt spinning of elastic fibers and modification of the impact resistance of polyacetals and as blend components for polycarbonates and acrylonitrile – butadiene – styrene (ABS) polymers [79], [80].

2.6. Economic Aspects

TPUs are produced in Europe, the United States, and Japan by the three large producers BASF, Bayer, and Noveon (quantities of > 20 000 t/a) and a number of medium and small producers (Table 7).

Table 7. Important producers of TPU and trade names

Region	Producer	Trade Name
Europe	Bayer	Desmopan
	Elastogran (BASF)	Elastollan
	Noveon	Estane
	Huntsman	Avalon, Irogran
	COIM	Laripur
	Mercquinsa	Pearlthane
USA	Bayer	Texin, Desmopan
	Noveon	Estane
	Huntsman	Krystalflex
	Dow	Pellethane
	BASF	Elastollan
Asia	Dainichi Seika	Resamine
	Nippon Miractran	Miractran
	DIC Bayer Polymers	Pandex, Desmopan
	BASF	Elastollan
	Hosung	Neothane
	SK Chemicals	Skythane

Almost all producers offer materials of differing hardness based on different polyols within several product ranges. In 2000, the estimated market volume was ca. 150 000 t/a. The regional distribution has a peak in Europe (40%), followed by North America (30%) and Eastern Asia (27%). The chances of growth are estimated to be positive in view of the possibilities for replacing rubber and plasticized thermoplastics by TPUs and the versatility of this class of materials.

2.7. Toxicology and Occupational Health

Since the production process involves polyaddition in a melt, very small quantities of byproducts are formed. Correctly dimensioned and efficiently functioning air extraction allows the permitted workplace concentrations for diisocyanates to be adhered to with certainty by producers and processors. Generally neither aromatic amines nor diisocyanates can be extracted from properly produced TPU articles. If only the allowable raw materials are used, TPUs comply with health authority guidelines for contact with foods (FDA: CFR 175.300, 175.105, 177.1680; European Commission Directive 2002/72/EC). Because of their good compatibility with blood and tissue, some products also fulfill the requirements of the ISO standard 10993/1 [82], [83].

3. Thermoplastic Copolyester Elastomers

Larry M. Ryan and Lawrence Plummer

3.1. Introduction

Thermoplastic copolyester elastomers are segmented block copolymers, consisting of repeating, high-melting, rigid “hard” blocks and amorphous, flexible “soft” blocks, which have a very low glass transition temperature. These polymers exhibit a remarkable combination of properties as a result of microphase separation of the hard block (in the form of crystalline domains) from the matrix of the amorphous soft blocks. The crystalline domains impart excellent mechanical properties (tensile strength, toughness, resistance to creep, good retention of properties at elevated temperature, etc.) and outstanding chemical resistance to the polymer. Concurrently, the amorphous domains provide exceptional flexibility and fatigue resistance over a broad temperature range. By varying the ratio of hard to soft blocks, products ranging from relatively rigid plastics to very flexible elastomers can be produced.

Copolyester elastomers are typically produced by condensation of an aromatic dicarboxylic acid or ester with a low molecular mass aliphatic diol and a polyalkylene ether glycol (molecular mass generally between 1000 and 4000) [84-86]. Reaction of the aromatic dicarboxylic acid with the diol leads to the crystalline hard segment phase, while the soft segment is the product of the diacid (or diester) and the long- chain glycol. Other combinations are possible, however (see Sections Long-Chain Polyether Soft Segments, Hydrocarbon Soft Segments).

3.2. Raw Materials

Polyester elastomers are produced from aromatic dicarboxylic acids or diesters, polyoxyalkylenes, and an excess of short- chain diols [84]. The most common raw materials follow:

Dicarboxylic Acids. *Terephthalic Acid* [100-21-0]. For production and properties, see ⟶ Teratogenic Agents.

2,6-Naphthalenedicarboxylic Acid [1141-38-4]. For production, see ⟶ Carboxylic Acids, Aromatic.

Polyoxyalkylenes. *Poly*(*tetramethylene oxide*); *poly*(*propylene glycol*) [25322-69-4]; *poly*-(*ethylene glycol*) [25322-68-3]; for production and properties, see ⟶ Polyoxyalkylenes.

Short-Chain Diols. *1,4-Butanediol* [513-85-9]. For production and properties, see ⟶ Butanediols, Butenediol, and Butynediol – 1,4-Butanediol.

Ethylene glycol [107-21-1]. For production and properties, see ⟶ .

3.3. Production

(see also ⟶ Polyesters – General Principles, ⟶ Polyesters – Production of Poly(Ethylene Terephthalate) from Dimethyl Terephthalate, ⟶ Polyesters – Production of Poly(Ethylene Terephthalate) from Terephthalic Acid, ⟶ Polyesters – Production of Poly(Butylene Terephthalate))

Polyester elastomers are manufactured by a *multistage melt polymerization process*. Soluble titanium alkoxides are generally used as catalyst. In the first stage of the process, all reactants are mixed and heated at atmospheric pressure to 190 – 220 °C to form a low molecular mass prepolymer. In the latter stages the prepolymer is converted to high molecular mass polymer by increasing the temperature to 250 – 260 °C while lowering the pressure to < 133 Pa to distill off the excess short- chain diol. The degree of polymerization is monitored by the viscosity change of the molten reaction mass by measuring the torque on the reactor agitator. To protect the polyether ester from oxidative degradation during synthesis and in end use applications, polymerization is usually carried out in the presence of an antioxidant. Hindered phenols such as Irganox 1098 (Ciba – Geigy) and Ethanox 330 (Ethyl Corp) or an aromatic secondary amine [i.e., Naugard 445 (Uniroyal)] are examples of antioxidants that are added during the preparation stage of the prepolymer. At the end of polymerization, the polymer is extruded, quenched, and cut into pellets. Predominantly hydroxyl and carboxylic acid end groups are produced by this process. The acid end groups are formed by the thermal cleavage of polymer chains or by degradation of a butanol end group with simultaneous elimination of tetrahydrofuran.

Both batch and continuous processes produce materials of sufficient viscosity to be fabricated by either extrusion or injection molding. However, a polymer with ultrahigh viscosity is required for blow molding operations and in extrusion processes where very precise dimensions are required. Generally, the polymer viscosities required for these methods of processing cannot be obtained by a melt condensation process. One technique used to manufacture ultrahigh-viscosity copolyester elastomers is *solid-phase polymerization* [87-90]. In this process the solid polymer is heated to just below its melting point under reduced pressure. This leads to the reaction of acid and hydroxyl end groups or of two hydroxyl end groups with elimination of water or short- chain glycols. They diffuse out of the polymer, and the molecular mass increases. A second method of increasing viscosity is by polymer chain extension in a postcompounding step. In numerous examples [91-93], diisocyanates have been used as chain extenders to increase the viscosity of low and moderate molecular mass polyesters through the reaction of the polyester hydroxyl end group to form a urethane.

Thermoplastic copolyester elastomers are stable for an indefinite period of time. However, they will absorb moisture, reaching equilibrium with existing atmospheric conditions very rapidly. Since the ester group hydrolyzes at processing temperature, these products must be dried thoroughly prior to fabrication. The moisture content should not exceed 0.1 wt % when molding or extruding [94].

3.4. Microstructure and Composition of Segments

3.4.1. *Short-Chain Ester Units (Hard Segments)*

The hard segment employed in the polyester elastomer strongly influences the load-bearing capabilities and processing characteristics of the polymer. Because of its high melting point, rapid crystallization, and low cost, the predominant hard

segment in commercial use is tetramethylene terephthalate (4 GT), an ester of 1,4-butanediol (4 G) and terephthalic acid (T). Hard segments based on ethylene glycol (2 G) and terephthalic acid (2 GT) are high melting and yield polymers with excellent physical properties. However, crystallization of this hard segment is very slow, requiring 36 h to completely develop the physical properties of the polymer. This limitation greatly reduces the usefulness of 2 GT thermoplastic elastomers in injection molding and extrusion applications [95]. WOLFE [96] has prepared a series of copolyester elastomers with a wide range of short- chain diols and compared their properties (Table 8). The properties of the elastomers resulting from 2 G, 3 G, (1,3-propanediol), and 4 G are very similar except for tensile and tear strength. Hard segments based on diols with five, six, and ten carbon atoms do not form high-melting crystals, and as a result, copolyesters made with these diols generally have inferior properties.

Table 8. Properties of 50 % alkylene terephthalate – PTMO terephthalate copolymer as a function of diol structure [96]

	Diol					
Properties	**2 G**	**3 G**	**4 G**	**5 G**	**6 G**	**10 G**
Melting point, °C	224	198	189	106	122	106
Shore D hardness	46	48	48	32	33	35
Stress at 100 % elongation, MPa	11.4	11.7	11.7	4.5	5.2	6.1
Tensile strength, MPa	45.5	22.8	48.4	15.4	13.5	15.5
Elongation, %	675	660	755	880	750	640
Tear strength, kN/m	42	15	48	25	18	7.8

Substituting a cycloaliphatic glycol, 1,4- cyclohexanedimethanol, for 1,4-butanediol produces a high-melting polyether ester elastomer that crystallizes somewhat slower than one containing tetramethylene terephthalate but rapidly enough to be blow or injection molded. Because of their slower crystallization characteristics, finished parts made of these elastomers are clear [97], [98].

Naphthalenedicarboxylic acid, in place of terephthalic acid, in combination with 1,4-butanediol provides products with improved thermal properties compared to their 4 GT counterparts [99]. Some mechanical properties such as tear strength are also improved. A major limitation in using naphthalenedicarboxylic acid in commercial thermoplastic copolyester elastomers, however, is its high price.

3.4.2. *Long-Chain Polyether Soft Segments*

The long- chain polyether soft segments are formed by reaction of poly(ether glycols) and diacids. The predominant poly (ether glycols) used in commercial thermoplastic copolyester elastomers are poly(tetramethylene oxide) (PTMO) and poly (propylene glycol) end- capped with ethylene oxide (EOPPG). In general, the chemical resistance and certain physical properties of thermoplastic elastomers, such as tear strength, are influenced by the poly(ether glycol) segment. For example, products based on PTMO have much higher tensile and tear strengths and significantly better resistance toward oxidative degradation than polymers made with EOPPG. Melting point, modulus, and hardness are generally independent of the type of polyether employed.

Because of their polarity, polymers made using poly(ethylene glycol) (PEO) show the greatest water swell, yet the least swell in nonpolar oils [100]. These products have high moisture vapor transmission rates.

A comparison of typical properties of thermoplastic polyester elastomers containing soft segments based on PTMO, EOPPG, or PEO is shown in Table 9 [101].

Table 9. Properties of 57 % 4 GT polyether elastomers as functions of polyoxyalkylene structure [101]

Properties	**Polyoxyalkylene**		
	PTMO	**EOPPG**	**PEO**
Nominal molecular mass	1000	1000	1000
Stress at 100 % elongation, MPa	13.4	11.7	13.2
Tensile strength, MPa	47.2	27.2	42.6
Elongation, %	660	675	705
Tear strength, kN/m	62	23	31
Volume swell, % [97]			
Water (3 d/24 °C)	0.5	1.0	17.0
	13.0	12.0	4.0

ASTM oil no. 3 (7 d/100 °C)

Through a novel set of reactions, polyethers end- capped with amino groups [102] also have been utilized to manufacture copolyester elastomers. These polyoxyalkylenamines are first converted to acid-terminated polyethers by reaction with benzene-1,2,4-tricarboxylic acid, followed by copolymerization with terephthalic acid and a short- chain diol. Since the backbone of the polyoxyalkylenamines is based on ethylene and propylene oxides, the resulting thermoplastic elastomers have properties similar to EOPPG-based products [103].

3.4.3. *Hydrocarbon Soft Segments*

Unsaturated straight- chain aliphatic carboxylic acids can be dimerized to form high molecular mass dicarboxylic acids, generally referred to as dimer acids [104]. When purified, these dibasic hydrocarbons have been used in place of poly (ether glycols) as soft segments in the preparation of thermoplastic copolyester elastomers. HOESCHELE [105] prepared several of these polymers and demonstrated the striking similarities with their polyether counterparts.

One major difference is that products based on dimer acid exhibit poor low-temperature properties because of their high glass transition temperatures. However, due to the hydrocarbon nature of the backbone, these polymers have much better heat aging characteristics and resistance to UV degradation. MCCREADY [106] has noted that the heat aging of thermoplastic polyether esters can be improved by using a mixed soft segment of dimer acid and poly(ether glycol).

3.4.4. *Polyester Soft Segments*

The use of low molecular mass polyester glycols as soft segments gives thermoplastic copolyester elastomers with improved heat aging characteristics and stability toward UV degradation compared to their polyether counterparts. However, the preparation of these products presents special problems because of the randomization that can occur between the hard and soft ester segments during synthesis. This negatively affects formation of blocks, and the resulting polymers are low melting with poor mechanical properties [107].

One approach to solving this problem is to react preformed hard and soft polyester seg-ments in the presence of a titanate catalyst until the reaction mass becomes clear. At that point the catalyst is deactivated by addition of a phosphorus compound [108]. On further processing into end use articles, very little ester exchange occurs between the hard and soft blocks, and as a result, parts with good mechanical properties are obtained. Generally, better results are obtained by chemical coupling of the blocks with diisocyanates [109] or acylating agents such as diacyl-bis-(*N*-lactams). A detailed description of diisocyanate coupling between poly(tetramethylene terephthalate) and various aliphatic polyester diols has been published by VAN BERKEL [107]. After deactivating the catalyst used for formation of 4 GT, coupling is carried out by using either toluene diisocyanate or methylene diisocyanate. A slight excess of isocyanate is used to obtain optimum mechanical properties. These thermoplastic polyester ester products show improved heat aging and UV resistance, but also have poor hydrolytic stability and stiffen much faster than polyether ester elastomers at low temperature.

3.5. Properties

Physical and Chemical Properties. Polymers prepared by the method described in Section Production have the molecular mass distribution expected from a condensation polymerization. A number-average molecular mass in the range of 20 000 – 25 000 can be obtained. The two-phase hard – soft segment structure of these segmented polyesters has been demonstrated clearly by differential scanning calorimetry [110]. By varying the ratio of these two segments, thermoplastic polyesters ranging from soft, transparent rubber-like elastomers to semirigid plastics can be prepared. Melting points ranging from 140 to 220 °C have been reported for polymers containing 20 – 80 wt % 4 GT [111]. As expected, the glass transition temperatures of this same series of polymers increase from – 70 to 25 °C.

Thermoplastic copolyester elastomers have good to excellent resistance to hydrocarbons. Products containing > 50 % 4 GT are particularly well-suited for contact with oil, grease, or hydraulic fluids. These polymers offer better resistance to hot hydrocarbons than nitrile rubber.

Resistant to

- Nonpolar fluids
  - Oil
  - Fuels
  - Hydraulic fluids
- Polar fluids at room temperature
  - Glycols
  - High molecular mass alcohols
  - Weak acids and bases

Not resistant to

- Hot glycols
- Hot alcohols
- Strong acids and bases
- Amines

Resistance to polar fluids, including water, acids, bases, amines, and glycols, is a function of both the composition of the polymer and the temperature of use. At > 70 °C, polar fluids attack the polymer.

Mechanical Properties. The predominant hard segment in thermoplastic copolyester elastomers is poly(tetramethylene terephthalate). WOLFE [96] has shown that a hard segment content of 30 to 80 wt % produces a wide range of useful products (Table 10). A complete summary of mechanical properties for these elastomers has been published [112].

Table 10. Properties of tetramethylene terephthalate – PTMO terephthalate copolymer as a function of tetramethylene terephthalate content [96]

Properties	Percentage 4 GT				
	30	**40**	**50**	**57.4**	**80**
Melting point, °C	152	172	189	197	212
Shore D hardness	34	44	48	54	70
Stress at 100 % elongation, MPa	5.9	8.3	11.7	13.4	24.4
Tensile strength, MPa	24.6	31.0	48.4	46.7	54.5

3.6. Blends

The low melt viscosity and good processing characteristics of thermoplastic elastomers facilitate their use in polymer blends to give products that are otherwise not easily obtainable. In many instances the properties of these blends are an average of the properties of the individual components, for example, the combination of poly(vinyl chloride) (PVC) and a polyester based on 4 GT and PTMO [113], [114]. The addition of 10 – 30 % of thermoplastic polyester elastomer provides PVC with improved heat resistance, low-temperature flexibility, and resistance to oils and fuels. Another important advantage is that the polyester elastomer cannot be extracted from the blend, which extends the service life of PVC molded parts.

In other instances, blends offer improved physical properties that are not obtainable by direct synthesis. Blending poly (butylene terephthalate) with a thermoplastic copolyester elastomer containing 58 wt % hard segment provides a polymer with improved low-temperature impact resistance compared to a directly synthesized polymer of identical composition [113]. The improvement in low-temperature properties is said to result from the incompatibility of the components of the resultant blend.

High-melting, crystalline thermoplastic copolyester elastomers can be softened (thus improving their low-temperature properties) by blending with an amorphous or very low melting polyester made from PTMO, 4 G, and a diacid [115]. Since the melting point of the resultant blend is similar to that of the unblended crystalline thermoplastic, evidence that the two components of the blend are not miscible is good. Soft thermoplastic copolyester elastomers can also be prepared by blending the polyester with ethylene copolymers. SHIH [116] reports blends with EPDM that retain the melting point of the polyester yet exhibit reduced stress – strain properties. In an extension of this work, blends of polyesters have been prepared with ethylene – carboxylic acid copolymers that had been partially neutralized [117]. This novel combination of polymers provides blends with enhanced melt viscosity, which greatly improves the processibility by blow molding and film extrusion of the thermoplastic copolyester elastomers.

Very efficient mixing is required to achieve good disperson of polyester homopolymers and thermoplastic copolyester elastomers because of their incompatibility [113]. If the materials being blended differ greatly in polarity, homogeneous blends can sometimes not be achieved unless *compatibilizers* are employed. These compatibilizers generally contain reactive functional groups to assist in dispersing the components of the blend. In two separate examples, polycarbonate resins having improved flexibility and impact strength were obtained by blending with copolyester elastomers. To obtain optimum properties, polystyrene grafted with organosiloxanes or styrene – butadiene copolymerized with acrylic acid derivatives has been used to compatibilize the blend components [118], [119].

3.7. Uses

Thermoplastic copolyester elastomers are available in grades ranging from soft, rubber-like to semirigid plastics. This provides customers with products covering a wide spectrum of load-bearing characteristics, flexibility, and low-temperature properties. These materials are simple to process and can be made into high-performance products by a variety of polymer-forming processes, including injection molding, extrusion, blow molding, rotational molding, and melt casting. All thermoplastic copolyester elastomers have sharp, well-defined melting points, crystallize rapidly, and have good melt stability.

Grades having a Shore D hardness of 50 – 80 have excellent chemical resistance, which makes them suitable replacements for specialty rubber such as nitrile and epichlorohydrin rubbers in hose and tubing applications. They can be extruded into long, continuous lengths with relatively low wall thickness, thereby providing lightweight constructions. Compared to competing flexible polyamide compounds, no plasticizer is required, so the material remains flexible over long periods of time. Overall, hose construction costs using thermoplastic copolyester elastomers are comparable to those using conventional rubber. This is due to the less expensive plastics processing techniques involved and the fact that thermoplastic copolyester elastomers require no postcuring [112].

The good impact strength and toughness, dimensional stability, and good paintability of thermoplastic copolyester

elastomers have been utilized in automotive applications to replace metal in exterior automotive bumpers and front and rear end spoilers. The use of thermoplastic copolyester elastomers is not limited, however, to the exterior of automobiles. Overmolded interior parts such as door handles having good “feel” properties also have been commercialized [120].

In a very demanding application requiring excellent flexural fatigue resistance, thermoplastic polyesters have replaced polychloroprene rubber in constant-velocity joint boot bellows for front-wheel-drive automobiles. In addition to the necessary flexibility, this application also requires a product with good thermal properties, high tear resistance, very good low-temperature properties, and resistance to lubricating greases [121].

Thermoplastic copolyester elastomers containing either EOPPG or PEO soft segments absorb significant quantities of water. Because of this characteristic, thin films produced from these materials have high moisture vapor transmission rates. In addition to their use in laminated films for moisture-proof sports and rain wear [122], [123], these materials have also found application in the medical field [124]. By varying the EOPPG or PEO content, a wide range of moisture vapor transmission rates can be obtained. These products are suitable for medical wound care treatment, transdermal patches, and surgical drapes [124].

3.8. Producers, Trade Names

Thermoplastic copolyester elastomers were originally introduced by DuPont in 1972 under the trade name Hytrel and are manufactured by DuPont in the United States and Luxembourg, and by DuPont – Toray in Japan. Other U.S. producers include General Electric (trade name Lomod), Hoechst – Celanese (trade name Riteflex), and Eastman Chemical Products (trade name Ecdel). Both copolyether esters and copolyester esters are manufactured by DSM in the Netherlands, under the trade name Arnitel, and by Toboyo in Japan, under the trade name Pelprene. Pibiflex is manufactured in Europe by Montedison. More recent manufacturers entering this field include two South Korean producers, Kolon Industries (Kopel) and Cheil Synthetics (Esrel).

4. Thermoplastic Polyamide Elastomers

Franz Erich Baumann and Jörg Lohmar

4.1. Introduction

Polyamides have been highly regarded thermoplastics for more than 50 years because of their high heat deflection temperatures, rigidity, and excellent resistance against solvents and aggressive chemicals. Their low melt viscosity permits easy processing, e.g., in injection molding. These and other positive properties have been transferred successfully to a greater or lesser extent to intrinsically softened polyamide elastomers.

In the early 1980s Chemische Werke Hüls (today Degussa) and Ato-Chimie (today Atofina) independently developed processes for the synthesis of multiblock copolymers containing sequences of different polyamides and various kinds of polyethers linked by either ester or amide bonds. These polyamide elastomers (PAE) – sometimes referred to as **P**oly **E**ther **B**lock **A**mides (PEBA) – behave like thermoplastic elastomers, i.e., they combine elastomeric properties over a wide range of temperature with an easy thermoplastic processibility. Because their properties are closely related to the basic polyamides PAE can be assigned to the high-performance class of thermoplastic elastomers.

4.2. Raw Materials

Polyamide elastomers consist formally of difunctional crystallizable oligoamides (hard segments) and difunctional soft segments having a low glass transition temperature. In many cases this sequential cocondensation is also a viable preparative procedure. Various embodiments of this “internal plastification” concept have been described such as (co-) polyolefin derivatives [125-131] and polysiloxane soft segments [132], in 2002 polycarbonate diols as soft segments have been described [133], however only polyether derivatives have become technologically important on a commercial scale so far [134-138].

Polyether diols and diamines undergo condensation with dicarboxylic acid terminated oligoamides to form sequential multiblock copolymers via polyesterification or polyamidation, respectively [137], [138]. The typical structural patterns of these copolymers can be simply visualized as shown below.

Typical PAE building blocks are polyamides with carboxylic acid terminal groups, e.g., PA 12 (polylaurolactam, number average molar mass, M_n = 600–4000 g/mol), polyethers with hydroxyl terminal groups or polyethers with amino terminal groups, e.g., polytetrahydrofurandiol (M_n = 600–3000 g/mol).

Oligoamide Unit. Oligoamides having carboxylic terminal groups are obtained by reacting excess dicarboxylic acid with a lactam, an aminocarboxylic acid or a nylon salt [138]. The dicarboxylic acid excess is tantamount to adjust a number average molar mass M_n of usually 600 to 4000 g/mol.

Polyether Units. *Polyether diols* applied in commercial PAE grades are based on polyethylene glycol (PEG), polypropylene glycol (PPG), and most frequently on polytetramethylene glycol (polytetrahydrofuran, PTHF). Polytetramethylene glycol diols have been commercialized in Europe and America, e.g., by Du Pont (TETRATHANE),

BASF (PTHF), or Great Lakes (POLYMEG). In Japan PTHF diol grades are manufactured, e.g., by Asahi Chemical or by Hodogaya.

Polyether diamines have been commercialized by Huntsman - formerly by Texaco – as JEFFAMINE D-grades (polypropylene glycol diamine) and as JEFFAMINE ED-grades (polyethylene glycol diamines).

4.3. Manufacture of Block Polyetheramides

The most important group of polyetheresteramides is derived from polyamide 12. The monomer basis is laurolactam which is converted to polyether block amides (PEBA) usually in a two-step process [134], [138]. The intermediate is an oligoamide dicarboxylic acid which is then condensed to a PEBA by forming ester or amide links (Fig. 8).

Figure 8. Two step formation of polyetheresteramide type PAE

4.3.1. *Polyetheresteramides*

The first step - ring opening polymerization of laurolactam - requires either acidolytic conditions, i.e., sufficiently high amounts of dicarboxylic acids [141] or the presence of water at high temperatures [142]. It may be advantageous to enhance the miscibility of oligoamide and oligoether by pressurizing the reaction mixture with water vapor [143].

The second polyesterification stage usually requires addition of a catalyst. Recommended classes of catalysts are dialkyltin(IV) compounds [138], phosphoric acid [144], tetraalkyl titanates [144], [145], tetraalkyl zirconates [146], tin(II)) salts [147], or antimony oxide [148], the latter also being applied as a mixture with tin and phosphorus compounds [149].

A *single-step batch synthesis* has been described [144], in which both lactam polymerization and polyesterification are performed in the same reactor: Usual polyamidation equipment can be employed, such as stirred autoclaves, provided that sufficient water vapor pressure up to 25 bar for the lactam cleavage can be applied and the reaction vessel can be evacuated for the second stage.

The one-pot synthesis, i.e., charging the reaction vessel with both polyamide forming monomers, including excess dicarboxylic acid, and polyether diols or diamines is always the method of choice when polyamide monomers more reactive than laurolactam are used: Drastic reaction conditions necessary for the ring opening of laurolactam – high temperatures over an extended period of time may cause thermal degradation of polyethers – can be avoided in these cases, in particular for caprolactam [140], aminocarboxylic acids [150], nylon salts, or equimolar mixtures of diamines and dicarboxylic acids [151] as polyamide forming monomers.

A continuous process applying *thin layer evaporation* has been described by Atofina [152-154], it requires, however, a separate synthesis of oligoamide dicarboxylic acid. This dicarboxylic acid terminated oligoamide is fed with a stoichiometrically equivalent amount of polyether diol via a static mixer into one or several thin-layer reactors equipped with rotating film-forming wipers. These elements are inclined to promote a reverse flow in the initial phase of the polyesterification, whereas in the final stages they are positioned in a way to promote downstream flow of the higher viscous melt [152]. The published procedure makes use of three sequential thin-layer reactors [152].

4.3.2. *Synthesis of Polyetheramides*

Condensation of oligoamide dicarboxylic acids with polyetherdiamines can be performed without the necessity of applying vacuum in the final phase of polycondensation [155], [158].

Polyamide elastomers based on this structural pattern have been developed by Ube, Ems (GRILAMID, ELY), and former Rhône Poulenc (DYNYL) [155], [159]. An additional benefit of the amide link instead of the ester group is the increased hydrolytic stability. The synthesis is usually performed batchwise in pressurized polyamide reactors. Both a single-step process [160] and a two-step process comprising a separate preparation of oligoamide dicarboxylic acids [161] have been described by Ube. Cocondensation of polyetherdiamines with low molar mass aliphatic diamines has also been described [162]. In the Ube synthesis a dimeric fatty acid is preferred both as a nylon chain terminator and as a link between polyetherdiamine segments.

Hybrid elastomers based on polyetheramides terminated with both amino and hydroxyl groups have been described [163], [164]: Reaction with isocyanates converts these polyetheramides into polyurethanes or polyureas, respectively.

Polyetheramides with very high melting points derived from nylon 46 segments have been prepared [165], [166] employing polyethers terminated by two primary amine moieties.

4.4. Physical and Chemical Properties

4.4.1. *Block Variations*

The properties of PAE can be varied and determined by the selection of both hard and soft block types (Table 11). The choice of hard blocks defines the upper service temperature, corresponding with the melting temperature of the base polyamide. Also water absorption, chemical stability, and density are determined by the chosen polyamide. The length of the hard blocks is controlled by the amount of chain limiting dicarboxylic acid and affects the melting range, the crystallinity and the transparency of the PAE.

Table 11. Variation of block types and correlations with PAE properties

Variable	Influenced property
Type of polyamide block:	melting range (upper service temperature)
	water absorption
PA 12, PA 11, PA 6, PA 66, PA 612	chemical stability
	density
Length of polyamide block	melting range (upper service temperature)
	crystallinity
	transparency
Type of polyether block:	glass transition temperature (lower service temperature)
water absorption, water permeability	
PTHF, PEG, PPG	electrostatic properties
	chemical and thermal stability
Length of polyether block	transparency
Block composition	rigidity, hardness, flexibility
Polyamide / polyether	

The choice of the soft segment type determines the glass transition temperature and, hence, the lower service temperature. Using hydrophilic soft segments such as polyethylene glycol or polypropylene glycol the moisture absorption and permeability is enhanced and permanent antielectrostatic properties induced. Soft segments with higher molar mass tend to phase separation causing lower transparency. Using polyethers with amino end groups (i.e., JEFFAMINE) the resulting polyetheretheramides have higher thermal and hydrolytic stability.

Finally, the block composition of polyamide and polyether blocks can be varied in a wide range and the resulting products encompass an outstanding range of rigidity. This is demonstrated in Figure 9 in terms of Shore hardness. PAE with high polyamide block contents have a Shore hardness D up to 70, i.e., close to polyamides themselves. With lowest polyamide block contents PAE can be very soft with Shore hardness A down to 60, hence, in the domain of soft rubbers. Such soft grades cannot be achieved using other TPEs.

Figure 9. Range of hardness for PAE

PAE = Polyamide elastomer; PUE = Polyurethane elastomer; PEE = Polyester elastomer; PA = Polyamide

Figure 10 shows a series of tensile stress-strain curves of PA 12-PAE with varied PA 12 block content. PAEs rich in PA 12 exhibit the typical behavior of thermoplastics with yielding. With increasing polyether content there is a transition to more and more elastomeric characteristics.

Figure 10. Stress-strain diagrams of PA 12-PAE from tensile tests according to ISO 527

4.4.2. *Morphology*

The specific mechanical properties of PAE are strongly determined by the phase morphology of the principally incompatible polyamide and polyether blocks. Four different phases had been identified by thermoanalytical methods and electron microscopy [167-169]. Differential scanning calorimetry revealed two melting signals, the dominant one corresponding with the melting of PA 12 blocks, the other one with a little content of crystallized PTHF blocks (Fig. 11). With decreasing level of PA 12 hard blocks the melting temperature drops indicating that the size of crystallites is becoming smaller. Amorphous phases have been detected by torsional vibration analysis. Figure 12 shows the loss modulus plots of the investigated PA 12 – PAE series. The maximum values of the plots correspond with the glass transition temperatures of amorphous phases. In a range of higher PA 12 block content, glass transition temperatures of two mixed amorphous phases with different block compositions are observed. At higher PTHF block content, the loss modulus plots are dominated by the signal of a PTHF-rich mixed phase.

Figure 11. Melting point diagrams (DSC) indicating two crystalline phases in PA 12-PTHF-PAE (T_m = melting temperature)

Figure 12. Loss modulus curves from torsional vibration analyses indicating two amorphous mixed phases in PA 12-PTHF-PAE (T_g = glass transition temperature)

With the aid of highly sophisticated contrast enhancing techniques, transmission electron microscopy (TEM) images were obtained demonstrating the unique morphology in PAE. Crystallized lamellae of PA 12 blocks form the same spherolitic superstructures as known from polyamides (Fig. 13). These crystalline superstructures form an interpenetrating reinforcing “physical network” for the amorphous mixed phase of PA 12 and PTHF blocks between the lamellae. At lower PA 12 content, only fragments of spherolites or single lamellae can be formed with a weak reinforcing effect on the soft amorphous PTHF-rich mixed phase (Fig. 14). For completeness it should be mentioned that PTHF-rich PEBA molecules build up a separate disperse phase due to the strong incompatibility between both blocks. This is the second amorphous mixed phase with the low glass transition temperature observed in torsional vibration analysis.

Figure 13. Transmission electron micrographs showing spherolitic superstructures of crystallized lamella in PA 12-PTHF-PAE (PA 12-rich PAE)

Figure 14. Transmission electron micrographs showing spherolitic superstructures of crystallized lamella in PA 12-PTHF-PAE (PTHF-rich PAE)

A number of the unique mechanical properties which distinguish PAE from all other TPE can be deduced from the interpenetrating network of crystallized polyamide blocks. This is valid for example for the lower temperature dependence of stiffness and elasticity compared to other TPEs.

4.4.3. *Outstanding Properties*

The specific advantages of PAE (PA 12-PTHF) compared with other TPE can be summarized as follows:

- Low density: 1.01 – 1.03 g/cm^3 (PUE, PEE: 1.14 – 1.25 g/cm^3),
- High stability against chemicals and solvents,
- Easy processing, coloring, and overmolding,
- Excellent ability to be decorated by thermodiffusion printing,
- Excellent cold impact strength,
- Wide range of hardness and flexibility,
- High elasticity and resilience,
- Low temperature dependence of mechanical properties,
- Excellent abrasion resistance (only surpassed by TPU),
- Highest service temperatures (especially PAE with PA 6 blocks).

Some of the outstanding properties of PAE are listed in Table 12 for a series of commercial products (VESTAMID E, Degussa AG) based on PA 12 and PTHF: The density (close to 1 g/cm^3) is up to 20 % lower than that of competing TPE. The flexural modulus of PAE comprises a full decade of magnitude, from 45 to 500 MPa. The cold impact strength of PEBA is excellent, as demonstrated by Izod notched impact data at –30 °C in Table 12. Very soft and medium soft PAE do

not break at all, stiffer grades with Shore hardness D >50 and tensile moduli above 200 MPa have still excellent toughness data.

Table 12. Major properties of PA 12-PAE compared with PA 12

Properties	Test-method	Unit	PA 12-PAE (VESTAMID E) with Shore hardness D (ISO 868)						PA 12
			30*	40	47	55	62	68*	72
Density at 23 °C	ISO 1183	g/cm^3	1.01	1.01	1.02	1.03	1.03	1.03	1.01
Tensile modulus	ISO 527 –1/–2	MPa	45	85	115	240	360	500	1500
Izod notched impact strength at –30 °C	ISO 180/1A	kJ/mm^2	no break	no break	no break	21	8	7	6
Heat deflection temperature									
Method A 10N	ISO 75-1	°C		45	45	45		50	
Method B 50N	ISO 75-2	°C		55	65	90	100		110
Vicat softening temperature Method A/10 N	ISO 306	°C	90	125	140	160	165	170	174

*Presently not commercially available.

The uptake of water is a crucial property for many PAE applications. In this regard PAE based on PA 12 and PTHF blocks do not differ significantly from PA 12 which has the lowest water absorption of all polyamides. With increasing polarity of polyamide and polyether building blocks the water uptake of PAE increases dramatically (Table 13). This creates a strong influence on the electrical behavior of the PAE. PAE with PA12 and PTHF-blocks are good insulators, while, e.g., PAEs based on PA 6 and polyethylene glycol blocks are permanent antielectrostatic due to their fast and high moisture uptake from the ambient air. High water uptake of PAE is not tolerable for applications where dimensional stability of parts is crucial. On the other hand PAE with higher absorption and permeability of moisture have found applications as antistatic modifier and, e.g., for moisture breathing film.

Table 13. Density and water absorption of various PAE in comparison

TPE-type	Density ISO 1183 g/cm^3	Water absorption (saturated) 20 °C / 65 % rh, wt %	20 °C / 24 h water storage, wt %
PA 12-PTHF	1.01 – 1.03	0.5	1.2
PA 6-PPG	1.10	2.4–2.8	6.1 – 6.4
PA 6-PEG	1.14	4.5	120
PUE*	1.14 – 1.25	0.1 – 5	0.5 – 15
PEE*	1.17 – 1.25	0.2 – 0.4	0.6 – 0.8
Rubber*	>1.20	0.6 – 0.8	0.1 – 15

*Strongly varying for different types.

4.4.4. *Chemical Resistance*

Due to their close relationship to polyamides PAE exhibit high stability against many chemicals and solvents compared with other TPE. The stability of PAE against diluted hydrochloric and sulfuric acid as well as bases should be especially noted. Rigid PAE grades show only low swelling in ASTM oil, even at 100 °C. This is also valid for hydraulic liquids, aliphatic solvents, and alcohols. With softer PAE grades the swelling in aromatic solvents and fuels is rather high, however, the mechanical properties are not affected dramatically.

4.4.5. *Processing*

PAE can be processed on standard equipment and with processing conditions usual for polyamides. For injection molding of PA 12-PAE melt temperatures of 190–230 °C are recommended for rigid grades and 170–210 °C for softer grades. Mold temperatures of 20–40 °C are suitable for all grades. Because of the very low melt viscosity and rapid crystallization, short injection cycle times are possible.

At extrusion temperatures of 210–230 °C, thin sheets, hoses, tubes, profiles, plates, and monofilaments can be processed. Other processing techniques applied for PAE are blow molding, rotational molding, thermoforming, and powder coating.

4.5. Uses

Since the polyamide block building monomers are rather expensive because of their multistep synthesis, PAE are ranking at the high end of the scale of prices of TPE together with PUE and PEE. As a consequence they are only used where one or more of their outstanding product and processing properties are required.

Polyamide elastomers are especially acknowledged for the construction of lightweight soles for specialists sport shoes. PAE are used primarily because of their low density, but also because of their good resilience, cold impact strength, and low temperature dependence of flexibility. The excellent processing and overmolding properties allow high sophisticated sole constructions. This has been applied for designs with sole parts of different stiffness and for decorative effects in overmolding of parts with different colors (Fig. 15). Even PA 12 based composites and PA 12 coated metal sheets have been incorporated in sole constructions. Recently the combination of overmolding and decorative printing techniques have been applied for new sports shoe soles constructions.

Figure 15. Sport shoe soles with overmolded PAE parts and PA 12 composites

Another main application field for PAE are winter sports goods such as lightweight ski boots or PAE films for decorative ski and snowboard surfaces. By means of thermodiffusion printing processes brilliant decorations are applied often on the bottom side of a PAE film. The colorants penetrate only about a 100 µm into the film of typical 500 µm total thickness. The film itself then acts as a protective layer for the decoration and the print motifs are almost indestructible (Fig. 16).

Figure 16. Design of skies with decorative PA12-PAE films, sublimation printed from the bottom side

Soft PEBA grades, with Shore hardness D below 40, have been used in such applications as straps of watches. Beside flexural properties, the dermatological compatibility, UV stability, and translucence of PEBA is striking. For frames of sunglasses, dermatological compatibility, easy processing, and coating stability of these elastomers is important. Medical uses are, e.g., catheters, or controlled drug release carriers. Hydrophilic grades are applied for moisture breathable film in surgical drapes and garments.

The excellent processing and demolding properties and the dimensional stability of PAE make them well suited for manufacturing precise moldings. PAE gear wheels (Fig. 17), for example, contribute to the noiseless operation of tape recorders or CD players.

Figure 17. Precisely molded PAE wheels for noiseless gears

For permanent antistatic housings PAE are compounded with special conductive carbon blacks which have still good impact resistance in spite of the necessary high loadings. Applications are permanently antielectrostatic parts, for example, castor wheels (Fig. 18), conveyor belts, rollers, and paint spray hoses.

Figure 18. Tough antielectrostatic PAE parts highly loaded with conductive carbon blacks

4.6. Trade Names

With a consumption of some 5000 t/a PAE play only a niche role in the TPE market. Suppliers for PAE are Degussa AG/Germany (VESTAMID E-grades, Shore hardness D 30–70, PA 12 base), Atofina/France (PEBAX, Shore hardness D 25–70 , PA 12 and PA 6 base, including hydrophilic grades), EMS Chemie/Switzerland (GRILAMID ELY, GRILON ELX, Shore hardness D 50–63, PA 12 and PA 6 base), and Ube/Japan (UBESTA, selected grades).

5. Styrenic Block Copolymers

Hans F. Vermeire

5.1. Introduction

Thermoplastic elastomers known as styrenic block copolymers (SBC) have emerged from developments and research in the organometallic-initiated polymerization of diene monomers in hydrocarbon solvents (⟶ Rubber, 3. Synthetic). Commercial block copolymers are essentially based on styrene, butadiene, and isoprene monomers. The first commercial quantities were produced by Shell in 1964 in its production plant in Torrance, Ca., and marketed under the trade name Kraton [170]. Worldwide capacity for styrenic block copolymers in 1993 was estimated at 500 000 t/a.

Styrenic block copolymers combine rubber performance with thermoplastic processibility on the basis of their specific structure. Anionic polymerization allows the selective polymerization of butadiene or isoprene and styrene in such a way that the resulting polymer is essentially a polybutadiene or polyisoprene molecule tipped at both ends with a polystyrene molecule [171]. Such a structure is commonly identified as ABA, where A represents the plastic and B the elastomer. More specific notations used are SBS or SIS polymers. Styrenic block copolymers with saturated rubber blocks are produced from SIS or SBS precursors by selective hydrogenation. This process converts the polyisoprene into poly(ethylene – propene) and the polybutadiene into poly(ethylene – butene). To provide rubber performance, the volume fraction of plastic (polystyrene) in these structures must be < 50 %, and commercial hydrogenated grades usually contain around 30 %. Newer variants of the styrene – ethylene/butene – styrene S – E/B – S or styrene – ethylene/propene – styrene S – E/P – S polymers are functionalized with maleic anhydride or other reactive comonomers. Functionalization levels are between 0.2 and 5 % and the reactive group is grafted onto the rubber mid block [172].

5.2. Synthesis

The first step in the production of SBCs is activation of purified styrene in a hydrocarbon solvent with butyllithium and subsequent anionic polymerization. The molecular mass of the first polystyrene block is determined by the butyllithium : styrene ratio (see Fig. 19). The formed living polymer, PS – Li, is then reacted with purified butadiene to form the second block. When all the diene has been converted, two routes can be followed to complete the formation of SBC:

1. Addition of a coupling agent to produce linear or branched copolymers
2. Addition of a second amount of styrene monomer to form the third block

Figure 19. Formation of block copolymers by anionic polymerization (A^- = butyl anion)

Technically feasible coupling agents include di-, tri-, tetra-, or multifunctional compounds that allow formation of a multitude of different polymer structures [173].

The procedure for production of the precursor for *saturated block polymers* is the same. To ensure a rubbery mid block after hydrogenation in the S – E/B – S polymer, a modifier is added during polymerization of the polybutadiene mid block to increase its vinyl content (1,2- content) (⟶ Rubber, 3. Synthetic) to approximately 40 % which will ensure optimum elastic properties after hydrogenation. This allows optimization of the ratio of ethylene and butene units in the hydrogenated polymer. After preparation of the precursor, polymer solution is transferred to the hydrogenation section where the double bonds of the polydiene are reacted with hydrogen in the presence of a catalyst.

Functionalized saturated block copolymers are made by extruder grafting of an S – E/B – S or S – E/P – S molecule. The polymer is contacted in an extruder with a peroxide to create free radical sites along the rubber mid block. These react in the extrusion step with a compound containing the functional group and a group able to react with the free radical sites (e.g., maleic anhydride). The process requires careful optimization of the amount of peroxide and reaction conditions to minimize polymer degradation.

The result of the polymerization process is a solution of polymer in hydrocarbon solvent. At this stage, additives such as stabilizers, antioxidants, or plasticizers can be added to the solution which is subsequently converted into solid polymer during finishing. The following systems are used industrially:

Direct Desolventizing. The polymer solution (cement) is introduced directly into a special vacuum extruder; the solvent is evaporated into a recovery system and the extruded polymer melt is face- cut and cooled at the die head of the extruder to form compact transparent pellets.

Coagulation with Steam. Cement is pumped to a vessel where steam is passed into the solution. The resulting coagulate separates from the solvent, and the polymer – water mixture is dried to remove water. The usual form resulting from the coagulation – drying route is referred to as crumb.

5.3. Properties

Thermoplastic rubbers based on styrenic block copolymer can be considered polybutadiene [or polyisoprene, poly (ethylene – butene), or poly(ethylene – propene)] tipped with polystyrene end blocks. Polybutadiene (butadiene rubber, BR) and polystyrene of sufficiently high molecular mass are incompatible, which forms the basis for the performance of these thermoplastic rubbers. At temperatures above the softening point of polystyrene the SBC molecule is quite mobile and can be melt processed by, e.g., extrusion or injection molding. On cooling, the PS end blocks separate from the BR

mid blocks, and two distinct phases are formed. The separate, discrete phase of the PS domains acts both as a cross-linking material and as a reinforcing filler analogous to the sulfur and carbon black in vulcanized rubber. Figure 20 shows an SBC where the PS domains hold together a rubbery BR network. The tensile strength (Table 14) and resilience data (Table 15) illustrate the truly rubbery behavior of a linear SBS polymer with a polystyrene content of 30 %.

Table 14. Comparison of tensile strengths of BR and SBS

Polymer	Tensile strength, MPa
Unvulcanized BR	0.2 – 0.5
Vulcanized BR	4.0 – 5.0
Vulcanized + carbon black reinforced BR	5.0 – 20.0
Unvulcanized pure SBS	30.0 – 35.0

Table 15. Resilience (Lüpke-rebound) of different polymers

Polymer	Resilience, %
Unvulcanized SBS	65
Vulcanized BR	65
Unvulcanized SIS	60
Vulcanized NR/IR	60
Vulcanized SBR	50
Vulcanized EPDM	45
Unvulcanized EVA (28 % VA)	40

Figure 20. Schematic phase structure of an SBS block copolymer

The *molecular structure* of an SBC can be varied by changing the proportion of PS in the base polymer. Furthermore the total molecular mass can be varied, but practical limits exist to the processibility in the melt. Figure 21 shows the effect of altering polystyrene content in a series of linear polymers. Polymers can be made that range from very low strength at low (10 %) PS content, through rubbery materials of about 30 % PS, to those with 80 % PS content that behave much like toughened polystyrene. SBC polymers can be linear or branched; branched types are usually higher in molecular mass than linear ones and have a higher melt viscosity at equal strength levels. Furthermore, a minimum molecular mass of the end block exists below which no phase separation occurs, no domain structure forms, and hence unsatisfactory properties are obtained [174]. A comparison of properties of polymers differing in the molecular mass of the PS blocks and in total molecular mass is given in Table 16.

Table 16. Properties of styrenic block copolymer structures with different PS block and total molecular mass

Polymer structure	Molecular mass		Viscosity	Strength
	PS block	Total		
Linear	12 000	80 000	low	high
Branched	12 000	160 000	medium	high
Branched	6000	80 000	very low	low

Figure 21. Stress – strain curves for various SBS copolymers

a) 80 % styrene; b) 65 % styrene; c) 50 % styrene; d) 40 % styrene; e) 30 % styrene; f) 10 % styrene

The *processing properties* of SBCs can be derived from their basic chemical structure. The molecular mass of commercially available grades varies from about 75 000 to 400 000. Their behavior in the molten state is similar to that of polyethylene and polystyrene, for example. However, even in the molten state the tendency to form PS domains persists, especially for those types with a saturated rubber mid block. *Melt processing SBCs* at higher shear rates leads to lower apparent viscosity; this effect is relatively independent of temperature (see Fig. 22). Reprocessing of SBCs at < 200 °C has little effect on their properties; saturated grades can be processed and reprocessed at up to 280 °C.

Figure 22. Viscosity – shear rate relationship at 200 °C

a) Clear polystyrene; b) SBS; c) polypropylene melt flow rate (MFR) = 5; d) S – E/B – S

Solution processing of SBCs is possible, provided that solvents of sufficiently high solubility are used to dissolve the PS end blocks. Solvents with solubility parameters between 8 and 10 are usually employed. Because of the easy solubility of SBCs, adhesive, sealant, and coating systems can be designed that have low viscosity and high solids content. A consequence of their good solubility in organic solvents is that the oil and solvent resistance of parts based on SBC is limited. However, their resistance to dilute aqueous solutions of the most commonly encountered chemicals is generally satisfactory.

The *service performance* of SBCs and the products derived from them is also related to their basic chemical structure. Because of their moderate molecular mass and their physical and reversible cross-linking, they flow under pressure and exhibit creep. Block copolymers with *BR or IR mid blocks* are unsaturated and sensitive to aging. Exposure to elevated temperature can result in polymer degradation with simultaneous decrease in viscosity and tensile strength. With the exception of black compounds, exposure to UV light for any length of time will result in discoloration and surface cracking, which becomes more pronounced on prolonged exposure. These block copolymers are also susceptible to ozone attack, and in shaped products at points with local stresses, microcracks develop on exposure to atmosphere containing ozone. The use of antioxidants, UV stabilizers, and antiozonants reduces these degradation effects to workable limits in end uses.

The *hydrogenated S – E/B – S or S – E/P – S types*, in contrast, have a saturated rubber mid block and are therefore highly resistant to degradation by oxidation, ozone, and UV light. They can be processed over a much wider processing temperature range.

5.4. Uses

Because of their rubbery characteristics (especially at low temperature), high strength, compoundability, and thermoplastic nature, SBCs are used in a variety of applications as highlighted in Figure 23.

Figure 23. Applications of styrenic block copolymers

SMC = sheet molding compounds; BMC = bulk molding compounds

On the left-hand side of Figure 23 the list includes outlets that use SBC as an additive or modifier for other materials. The polymers are delivered to the end user who will incorporate them in his existing process. The right-hand column lists applications that utilize a compounded product with performance tailored to the specific end use and plastic conversion technology. A comprehensive review of the applications of thermoplastic rubber is given in [175], [176].

5.4.1. *Adhesives, Sealants, and Coatings*

Adhesive properties are determined primarily by the styrenic block copolymer type chosen for a typical application. SBS polymers with high cohesive strength (high polystyrene content) are commonly used in contact adhesives, whereas SIS polymers with low polystyrene content that can be tackified easily are preferred for pressure-sensitive adhesives. For applications in hot melt form, low molecular mass polymers with a high melt flow rate are selected. When high UV resistance is required, hydrogenated block copolymers should be considered as base polymer. Furthermore, adhesive properties are also determined by the nature and the concentration of the various resins and plasticizers used and their degree of compatibility with the respective mid or end block phase of the block copolymer [177].

Pressure-sensitive adhesives are materials that remain permanently tacky and adhere instantaneously to solid surfaces on the application of light pressure. Major applications are tapes and labels. Tapes require high shear strength and holding power, while labels require less shear strength but good convertibility. For general-purpose solvent-based pressure-sensitive adhesives, SIS block copolymers are combined with resins that are compatible with the mid block, such as wood rosins, polyterpenes, or synthetic hydrocarbon resins. A typical composition is shown in Table 17, formulation no. 1. The formulation for an adhesive used for permanent labels is given in Table 17, formulation no. 2. Pressure-sensitive adhesives for peelable labels have a relatively high cohesive strength and a low peel strength (Table 17, no. 3). Labels that are applied under cold conditions must have a low T_g, and formulations usually contain low amounts of high-melting resin but large proportions of plasticizer (Table 17, no. 4).

Table 17. Pressure-sensitive adhesive formulations and properties

Composition, property	Formulation number			
	1	2	3	4
Parts by weight				
SIS polymer *	100	100	100	100
Piccotac 95	90		25

Probe tack, N	10	>10		10
Loop tack, N/25 mm	25	30	8	27
180° peel adhesion, N/25 mm	17	15	5	16
SAFT, °C	115	100	80	100
T_g (Fox), °C	–20	–19	–33	–29

* Kraton D-1107 from Shell Chemicals.

In outdoor applications where the adhesive must withstand UV light, saturated block copolymers are employed. Pressure-sensitive adhesives with very high temperature resistance can be obtained by UV or electron beam curing (⟶ Radiation Chemistry). A special polymer developed by Shell for this application is Kraton D-1320X. The shear adhesion failure temperature (SAFT) of a pressure-sensitive adhesive based on this polymer is increased from 80 °C to ca. 140 °C by either UV or electron beam curing [178].

Contact adhesives are applied as liquid onto one or two substrates; after a certain time to allow partial evaporation of the solvent (open time) the coated substrates are pressed together to form a strong bond. SBCs are ideal for these types of adhesives because they offer high cohesive strength without vulcanization and are readily soluble in many solvents. For some applications, the contact adhesive is allowed to dry completely to a tack-free nonblocking adhesive film. Exposure to heat reactivates the adhesive, and a firm bond forms under pressure. Large surfaces are commonly coated by spraying with a uniform adhesive layer (e.g., on flexible foams used in the furniture and automotive industries). Because of their molecular structures, SBC-based adhesives combine high strength with low viscosity and ease of spraying. A variety of melt adhesives are used in the construction of hygienic products such as disposable diapers, sanitary napkins, etc. These adhesives can be applied by spray or slot-die coating techniques. Selection of the styrenic block copolymer depends on the properties required and the application technique used.

Sealants. Styrenic block copolymers with *saturated rubber mid block* are ideally suited as base polymers for both hot-melt and solvent-based sealants that require resistance to long-term degradation and weathering [179], [180].

Coatings. In several applications, SBCs are used to formulate *protective coatings* based on solvent systems, but the trend is toward solvent-free systems, for example, in chemical milling (⟶ Imaging Technology – Photochemical Machining).

5.4.2. *Modification of Bitumen*

The addition of SBCs to bitumen increases its upper and decreases its lower operating service temperature, which results in substantial performance improvement in applications such as roofing felts, waterproofing membranes, and asphalt pavement. Selective development of SBS polymers has enabled bitumen to maintain its strength and integrity at elevated temperature without flowing and to remain flexible and ductile at temperatures well below the freezing point [181]. Moreover, SBCs greatly enhance the lifetime of bitumen-based products (e.g., roofing felts). This is achieved by development of a three-dimensional network. To optimize the effect of SBS addition, bitumen with the right degree of compatibility must be selected to ensure effective formation of the elastomer network. For roofing felts, SBS addition levels are commonly between 8 and 12 %. Blending into the bitumen is carried out at 170 – 190 °C. For fast dissolution, especially when low-shear paddle mixers are employed, SBS polymer is ground to a powder with particle size of ca. 1000 µm. For most applications, high-shear mixers are used with regular polymer crumb [182], [183].

The use of polymer-modified bitumen for asphalt pavements is growing rapidly and offers large potentials for SBC in the future. The SBS addition levels for road applications are lower than for roofing: typically 3 – 7 %. In addition to improved deformation and flexibility, laboratory data clearly demonstrate that the durability of asphalt roads is increased by addition of SBS polymer [184]. Many test roads have been installed that are being monitored to gain experience and evidence for performance under practical conditions. For documentation of the most important practical experiences so far, see [185-191].

5.4.3. *Compounded Products*

As mentioned earlier, end use parts that are made via established plastic processing techniques do not employ pure SBC polymers but rather — like traditional vulcanized rubber — compounded and end use-tailored compositions. Depending on their requirements, such compounds have hardnesses in the range from 35 Shore A to as high as 55 Shore D. The actual SBC content can be as low as 15 wt % but is usually between 25 and 40 wt %. SIS block copolymers are rarely used as base polymer for compounds. The main classes of compounding ingredients include the following:

Mineral oil is used as plasticizer to increase flow and reduce cost. Paraffinic or naphthenic oils are used that compatibilize with the rubber mid block. Aromatic oils or polar plasticizers such as dioctyl phthalate (DOP) are avoided because they strongly plasticize the end blocks and reduce strength.

Polystyrenes are important compounding ingredients to increase hardness, strength, and wear resistance, particularly in SBS polymers. Both clear and high-impact polystyrenes are used.

Polyolefins, particularly polypropylene, are important ingredients in S – E/B – S and S – E/P – S block copolymers.

Fillers, mainly cheapeners and nonreinforcing types, are used to decrease cost and increase hardness. They also increase density, which is exploited in formulations for sound-deadening applications.

Additives such as antioxidants, UV stabilizers, and antiozonants, as well as additives that induce special effects, can be used. Examples are pigments, surface-active slip agents, blowing agents, and antistatics.

Compounding is carried out at elevated temperature and at shear conditions that result in a fine, stable dispersion of the various ingredients. Compounding equipment originates from both the rubber industry with two-roll mills, Banbury-type internal mixers, and Farrel continuous mixers, and the plastic processing industry with mainly single- and double-screw compounding extruders. Modern compounding plants are fully instrumented robots in which a twin-screw corotating compounder with a length : diameter ratio (L : D) up to 42 is the key unit. Screw types with feeding, kneading, homogenization, and venting sections are designed for the specific compounding operation. Ingredients are added either as preblended mixture or via separate weigh feeders and oil injection pumps. The granulating section at the end of the extruder is important because it is responsible for formation of the homogeneous, free-flowing pellets required in subsequent plastics conversion equipment. Depending on line capacity and product characteristics (i.e., soft or hard), die plates with knife cutters, water-ring pelletizers, underwater pelletizers, or a strand die with water cooling bath and rotating knife granulator, can be used.

Detailed compositions and selection of base polymers have been published by SBC suppliers in the form of technical bulletins or formulating guides. Compounding know-how and formulations based on SEBS or SEPS polymers is rather specific [192]. Table 18 lists properties of typical SBC-based compounds tailored for selected end uses. The largest volume of SBCs in compounded form is consumed by the footwear industry. Here, SBS-based compounds are established mainly as high-quality soling materials. An important aspect is the multitude of colors that can be combined in shoe design. Compounding aims to optimize the end products with respect to melt flow rate (for ease of processing), high abrasion resistance (for durability), and good resistance to repeated flexing. Hardness for most typical soling materials falls within the Shore A 55 to 75 range.

Table 18. Properties of compounded SBCs

Property	Reference no.*, base SBC polymer				
	1 SEBS	2 SBS	3 SEBS	4 SEBS	5 SEBS

* 1 = Transparent medical molding; 2 = soling material; 3 = automotive sound deadening; 4 = high-temperature performance; 5 = electrical wire insulation.
** UL = Underwriters Laboratories code.

Compounds designed for use in medical devices and articles intended for food contact are also important outlets and take advantage of the high purity of polymers made by anionic polymerization. SBS- and SEBS-based compounds which meet the requirements set in the United States by the FDA and in Germany by the BGA, are used for syringes, tubing, bottle nipples, stoppers, i.v. bag systems, etc. Contact of SBS and SEBS with fatty food is restricted.

Thermoplastic rubber products can be recycled, and scrap, trimmings, and off-specification parts can to a certain extent be reintroduced in the manufacturing stream.

5.4.4. *Modification of Plastics*

Most plastics are brittle and lack impact resistance, particularly below 0 °C. Rubber is added to achieve

1. Increased impact strength (Izod, Charpy, FWIS, Dart, etc.) especially at low temperature
2. Increased environmental stress corrosion resistance

The addition of a rubber to a thermoplastic also changes properties such as stiffness, tensile strength, yield modulus, surface friction, softening point, clarity, electrical properties, vapor transmission, and gloss.

With many plastics, an impact resistance improving rubber fraction can be incorporated in the polymerization reaction. Examples are propene – ethylene copolymers, high-impact polystyrene (HIPS), and ABS. Nevertheless, styrenic block copolymers are used as melt-blended component in plastics that do not allow reactor modification or to obtain impact performance in excess of that achievable in the reactor. Polystyrenes are often compounded with flame-retarding additives and then require the addition of SBS polymer to compensate for the loss in impact strength due to addition of the flame retardant [193]. Engineering plastics require processing temperatures beyond the operating range of SBS. Here, saturated SEBS and SEPS block polymers are used, especially as modifiers in polycarbonate (PC) and poly(phenylene ether) (PPE). The more polar engineering plastics such as polyamides and polyesters can be adequately impact modified by SEBS or SEPS functionalized with maleic anhydride [194].

Styrenic block copolymers are also capable of compatibilizing different and dissimilar plastics into useful and workable blends. Addition of SBS or SEBS to a blend of polystyrene and polypropylene or polyethylene, for example, creates a ductile material that can be extruded or molded without the delamination or phase separation ecountered in the absence of block polymer addition [195]. Similar results are obtained when SEBS is used in blends with polycarbonate and polypropylene, as well as polyethylene – poly(ethylene terephthalate) (PETP) blends. Functionalized block polymers are good compatibilizers for, e.g., polyamides and polypropylenes. SBCs can also be used in thermoset resin systems, particularly as additives for sheet molding or bulk molding processes with unsaturated polyesters. Moldings modified with specifically developed SBS or SEBS polymers to control shrinkage show high-quality surface appearance [196], [197].

The use of SBCs as compatibilizers for mixed plastic streams is becoming more and more important with respect to waste management and upgrading and compatibilization of used plastics [198].

Abbreviations for polymers and monomers:

2G: ethylene glycol

2GT: dimethylene terephthalate, ethylene terephthalate

3G: 1,3-propanediol

4G: 1,4-butanediol

4GT: tetramethylene terephthalate, butylene terephthalate

5G: 1,5-pentanediol

6G: 1,6-hexanediol

10G: 1,10-decanediol

ABS: acrylonitrile – butadiene – styrene copolymer

BR: butadiene rubber

DOP: dioctyl phthalate

DVA: dynamically vulcanized alloys

EOPPG: poly(propylene glycol) capped with ethylene oxide

EPDM: ethylene – propene – diene terpolymer

EPM: ethylene – propene copolymer

EPR: ethylene – propene rubber

EVA: ethylene – vinyl acetate copolymer

H_{12}-MDI: 4,4′-dicyclohexylmethane diisocyanate

HDI: hexamethylene diisocyanate

HIPS: high-impact polystyrene

IR: isoprene rubber

MDI: 4,4′-methylene diphenyl diisocyanate

NDI: 1,5-naphthalene diisocyanate

NR: natural rubber

PAE: thermoplastic polyamide elastomer

PB: polybutadiene

PC: polycarbonate

PEO: poly(ethylene glycol); poly(ethylene oxide)

PETP: poly(ethylene terephthalate)

PP: polypropylene

PPE: poly(phenylene ether)

PS: polystyrene

PTMO: poly(tetramethylene oxide)

PVC: poly(vinyl chloride)

RTPO: reactor thermoplastic polyolefins

S – E/B – S, SEBS: styrene – ethylene/butene – styrene copolymer

S – E/P – S, SEPS: styrene – ethylene/propene – styrene copolymer

SBC: styrenic block copolymers

SBS: styrene – butadiene – styrene block copolymer

SIS: styrene – isoprene – styrene block copolymer

T: terephthalic acid

TODI: 3,3′-tolidine-4,4′-diisocyanate

TPE: thermoplastic elastomer

TPNR: thermoplastic natural rubber

TPO: thermoplastic polyolefin elastomer

TPR: thermoplastic rubber

TPU: thermoplastic polyurethane elastomer

TPV: thermoplastic vulcanizates

VA: vinyl acetate

Other abbreviations used
BMC: bulk molding compound

MFR: melt flow rate

SAFT: shear adhesion failure temperature

SMC: sheet molding compound

T. S.: tensile strength

U. E.: ultimate elongation

UL: Underwriters Laboratories code

1. Introduction

Typical of thermosetting plastics (thermosets) is that they are formed in the processing mold from moderately large molecular building blocks (reactive precursors) by chemical reaction. This contrasts with thermoplastics, where the finished high-molecular material is merely physically remelted in the mold. That also explains the main difference between these two kinds of plastics: thermosets no longer melt and are processed at temperatures far below their application temperatures; thermoplastics can be remelted and must therefore always be processed at temperatures far above their temperatures of use.

In German, the thermosets were formerly known as *Pressmassen* (compression-molding compounds) since they were processed by compression molding. Thermoplastics were known as *Spritzgussmassen* (injection molding compounds) since they were processed by injection molding. Since the mid-1960s thermosets have also been processible on injection molding machines, so the term *Formmasse* (molding compound) has been introduced whereby a distinction is made between curable and noncurable molding compounds (thermosets and thermoplastics, respectively).

The classical thermosets, which mainly are discussed here, are based on phenolic, urea, or melamine resins. These were followed by others based on unsaturated polyester, diallyl phthalate, epoxy resin, or silicone resin. Polyurethanes (→ Polyurethanes) and polyimides also can be thermosets. Strictly speaking, even cross-linked thermoplastics can be regarded as thermosets.

A comprehensive survey of the wide field of the thermosets is provided in [1]. Also discussed there are future developments based on nadimide- (polyimide), maleimide- and acetylene-terminated thermosetting polymers.

History [2]. Compression-molding compounds were the first fully synthetic plastics. Resins were manufactured from phenol and formaldehyde according to the patents of L. H. BAEKELAND as early as 1910 and, after mixing with fillers, cured to plastics by applying heat and pressure. Phenolic resin compression molding materials were initially based on phenolic resols (one-step resins), and later (in the 1920s) on novolacs ("two-step resins") (see also → Phenolic Resins). The use of novolacs with curing by hexamethylenetetramine was an important development (fast-curing molding compounds), since it also improved the manufacture and the storability.

In the late 1920s, the urea resin compression molding compounds came onto the market and made white and colored light-resistant compression moldings possible. At the end of the 1930s melamine resin compression molding compounds were introduced, which made good water resistance possible.

Compression-molding compounds based on unsaturated polyester resins (see → Polyester Resins, Unsaturated) and epoxy resins (see → Epoxy Resins) became widespread after World War II, the polyester resin compression-

10.1002/14356007.a26_665

molding compounds, at first being only wet-compounded. Today, dry, free-flowing polyester resin compression molding compounds also have gained major importance.

Molding compounds are generally unshaped products which can be processed by pressure and temperature to form moldings.

In the thermosetting plastics, because of the chemical curing process, the composition of the molded material differs from that of the molding compound. In the case of thermoplastics, the finished plastic is processed, and only remelting takes place in the mold.

Classification. From the beginning, thermosetting molding compounds were compounded from binders and fillers. This was done to remove the brittleness from the moldings, to economize on resin, and to broaden the range of applications of the materials. An extremely wide variety of materials are used as fillers. The term filler can refer to nonreinforcing and reinforcing fillers.

Fillers can be classified into inorganic and organic, into powder, fibrous, and lamellar types (see Table 1) [3].

These fillers can be combined with various binders. It is also possible to compound combinations of binders with one filler or combinations of fillers with a single binder. Finally, there is also the possibility of combining mixtures of several binders with the mixture of several fillers.

The binder (resin) can be manufactured from diverse molecular building blocks and by various reaction mechanisms (see Table 2) [4]. Today, phenolic resins, urea resins, melamine resins, unsaturated polyester resins, and epoxy resins are widely used. Resins based on diallyl phthalate or silicones are less important.

The curing or cross-linking process in the mold can proceed by other chemical reactions than the manufacture of the resin itself. Polycondensation, polymerization, or polyaddition can be involved. In case of polycondensation, low-molecular substances (e.g., water) are split off, whose vapor pressure at processing temperature must be compensated for.

The properties of the cured molded material are the sum of the properties of the resins and of the fillers. Thus for a given filler, the typical binder properties, and for a given binder typical filler properties are observed. Therefore, resin-determined and filler-determined properties must be differentiated.

Standardization. For the standardization and monitoring of thermosetting molding compounds in Germany, the Technical Association of Manufacturers and Processors of Plastics

Table 1. Fillers for thermoset molding compounds

	Particle form	Example	Advantages			Disadvantages
Inorganic	powder short fibers long fibers platelets	stone powder mineral fiber glass fiber mica	high thermal stability	uniform distribution, high mechanical values	high density	low mechanical values, orientation
Organic	powder short fibers long fibers platelets	wood flour cellulose textile threads macerated fabric	low density	uniform distribution high mechanical values	low thermal stability	low mechanical values orientation

Table 2. Resins for thermoset molding compounds

	Symbol	Resin structural units	Resin-forming reaction	Cross-linking reaction	Reaction product split off on cross-linking
Phenoplastic	PF	phenol and formaldehyde	polycondensation	polycondensation	water
Aminoplastic	UF	urea and formaldehyde	polycondensation	polycondensation	water
	MF	melamine and formaldehyde	polycondensation	polycondensation	water
Unsaturated polyester	UP	unsaturated dibasic acid and diol	polycondensation	polymerization	none
Epoxide	EP	bisphenol and epichlorohydrin	polycondensation	polyaddition with diamine or dibasic acid	none
Diallyl phthalate	DAP	monomeric diallyl phthalate	polymerization	polymerization	none

Molding Compounds (Technische Vereinigung der Hersteller und Verarbeiter von Kunststoff-Formmassen) has been established to promote cooperation between raw material manufacturers and processors. Type tables with minimum requirements for several important properties of the molded materials have been drawn up. These properties are tested on defined test specimens according to DIN specifications. The tables, also specify the binder and filler for each type. The most important DIN standards are DIN 7708 (phenolics and aminoplastics) and DIN 16 911 (polyester resin molding compounds). For epoxy resin molding compounds, DIN 16 912 has been withdrawn owing to the rapid development in this field.

Beyond the type values listed in the DIN specification tables, a further series of properties of the molding compounds is defined. In the case of the phenolics, this is information on the base resin, resin content, and color. For example, a molding material of Type 31 might carry the designation 31-1449, where the first two digits indicate the type according to DIN 7708. The third digit indicates phenolics as base resin, the fourth defines a minimum resin content and the last two the color:

3 = 35 % resin content
4 = 40 % resin content
5 = 45 % resin content
6 = 50 % resin content
7 = 55 % resin content
8 = 60 % resin content
00 – 09 = white, yellow, natural
10 – 19 = light brown to dark brown
20 – 29 = red to mahogany
30 – 35 = green
35 – 39 = blue
40 – 49 = grey to black

An additional definition is sometimes appended to the type designation (e.g., 51.5):

.5 = electrically high-quality
.7 = suitable for tableware for eating and drinking
.8 = content of volatile acids < 0.18 %
.9 = ammonia free

Attempts to develop a system analogous to DIN 7708 for the quality assurance of thermoplastics failed. This was partly due to the difficulty of producing standard test specimens by injection molding. To offer designers the possibilities of comparing the diverse plastics, in Germany the four largest plastics manufacturers, BASF, Bayer, Hoechst, and Hüls, have created the CAMPUS System (Computer-Aided Material Preselection by Uniform Standards), which has been joined by more than 20 international chemical companies. Since then thermoset manufacturers have also decided to use this system on grounds of rationalization, especially since the single-point values originally used for quality assurance are now supplemented by curve diagrams.

The CAMPUS System is offered in the form of diskettes free of charge by the participating firms and can be run on IBM-compatible PCs.

In the course of internationalization, DIN standards have already in many cases been replaced or supplemented by ISO or EN standards [5].

2. Manufacture

Despite the great variety of possible thermosetting molding compounds, only a few processes are used in their manufacture. The binder (resin) must be converted to the liquid state so that good impregnation of the fillers is possible. This is referred to as the fusion process if liquefaction is carried out by melting the resin, and as the liquid resin process if the resin is already liquid at room temperature or is used in solution in water or organic solvents [3].

2.1. Fusion Process

In the fusion process (Fig. 1) a premix is produced from finely ground solid resin, fillers, colorants, lubricants, and release agents, etc. Examples of recipes (in wt %) follow:

Type 31 (PF)	
Phenol novolac	43
Hexamethylenetetramine	7
Wood flour	45
Magnesium oxide	1
Zinc stearate	2
Dyes	2
Type 150 (MF)	
Solid melamine resin	50
Accelerator	0.5
Wood flour	45
Zinc stearate	1.5
Dyes	3

Figure 1. Compounding of thermoset molding compounds by the fusion process
a) Premixer; b) Premix; c) Rolls; d) Screw kneader; e) Cooling; f) Precomminution; g) Grinding; h) Sieving; i) Classifying; j) Mixing

The premix is then compounded discontinuously or continuously on roll mills or extruders to form the thermoset molding compound. The roll mills have two contrarotating steel rolls, up to ca. 3 m long, heated by steam, high-pressure water, oil, or electric (for smaller rolls), and rotating at different speeds. Their roll gap, a few millimeters, is variable. The rolls differ in temperature (e.g., 90 °C for the front and 150 °C for the back roll), so that on feeding the premix a layer (sheet) forms on the (cooler) rolls covering itcompletely. On passage of the sheet through the narrow gap between the rolls, the material is kneaded and mixed as a result of the different roll speeds. In addition, a bank forms on the roll gap rotating contrary to the front roll. On the roll mill, the fillers are impregnated with the binder, the material is homogenized, and in the case of polycondensation compounds (phenolics and aminoplastics) also precross-linked.

The precross-linking is continued until a thermoset molding compound has been formed that the processor can still process in his specific mold with the forming pressure available to him. This enables increased savings of energy and time to be made at the processor's works.

In addition, extensive precondensation also improves the properties of the molded material, such as surface gloss, electrical properties, shrinkage and post-shrinkage behavior. Compounding on roll mills can be carried out discontinuously or continuously. In the discontinuous process, when the sheets have reached the required degree of precondensation they are cut open along the roll and pulled off. In the continuous process, the premix is fed continuously in the middle or on one side of the roll, and the sheet formed is cut off in narrow continuous strips at the roll edge.

In the extrusion process, single- or twin-screw machines or planetary screw extruders are used. In this case the premix is usually processed in large batch premixers.

Processing on the extruders is continuous. In both the roll-mill and extruder processes, the sheet or lumps formed are cooled, giving a grindable product. From this, a granular molding compound of defined grain size is obtained by breaking, milling, and sieving.

For the fusion process, powder or short-fiber fillers such as wood flour, stone powders, and glass fibers, are best suited. Long-fiber fillers are broken down by the high shear forces in the roll gap. Materials manufactured by the hot melt process include phenolic resin molding compounds (PF) of Types 11 (stone powder), 31 (wood flour) according to DIN 7708; the melamine – formaldehyde (MF) and melamine phenol (MP) Types 150 (wood flour), 180 (wood flour), and 155 (stone powder); and the polyester resin Types (UP) 802 and 804 (short glass fibers) according to DIN 16 911. The UP compounds are not precured since hardening by polymerization takes place only in the molding tools.

2.2. Liquid Resin Process

The liquid resin process (Fig. 2) is used mainly for compounding thermosetting molding materials that contain long-fiber or macerate fillers (coarse-structured materials). Kneaders (e.g., sigma kneaders, which bakeries also use) or edge mills are used as mixing units. The compounded materials can be removed in the dough state after mixing and impregnation. Examples are Types 801 and 803 (DIN 16 911), which are compounded with liquid, styrene-containing unsaturated polyester resins and contain long glass fibers.

Figure 2. Compounding of thermoset molding compounds by the liquid resin process
a) Kneader; b) Edge mill; c) Drying; d) Cooling; e) Coarse grinding

The compounds can also be dryed and further condensed, as in the case of the phenolic of Type 71 (textile fibers) or 74 (textile macerate) or the aminoplastic Types 153 (textile fibers) and 154 (textile macerate) (DIN 7708).

Discontinuous tray driers or continuous-flow driers can be used for drying and further condensation. By suitable choice of temperature and drying time, the flow – cure behavior of phenolics and aminoplastics can be adapted to the requirements of the processor. When using solvent-containing resins, however, care must be taken that prior to further condensation the solvent can escape from the molding compound particles. If solvent residues are trapped because drying process has not been carried out properly, surface defects can occur on molding.

The liquid resin process is mainly used for the mild impregnation of long-fiber fillers, but it also allows low-resin molding compounds to be produced if the liquid resin is highly diluted by solvent.

2.3. Other Processes

A number of special methods exist. For example, a turbomixer (Fig. 3), which permits very short mixing times, can be used in the liquid resin process. Turbomixers are also suitable for the hot melt process since the large amount of mechanical energy introduced can lead to fusion of the finely ground resin. In addition to impregnation of the filler, the mixture is agglomerated to dust-free granules. As a result, subsequent grinding can be dispensed with, and particularly free-flowing granules are obtained. In addition, recycling of dust and oversize grain to the process, which is otherwise necessary for granule production, is unnecessary.

Figure 3. Compounding of thermoset molding compounds in a turbomixer
A) Wet mixing and impregnation; B) Dry mixing and impregnation
a) Turbomixer; b) Drying; c) Coarse grinding

3. Commercial Forms and Manufacturers

Thermoset molding compunds are supplied in diverse forms, from dust-fine material through various grain sizes up to briquetted grades, depending on the mechanical demands made on the molding to be manufactured. Thus, a material compounded with coarse-structured filler cannot be supplied in a fineground form without loss of strength. Fine grinds are therefore useful mainly in recipes containing powdered filler or with short-fiber fillers.

Conventional size reduction by crushers and mills (e.g., hammer mills, pinned disk mills, cutting mills etc.) of the brittle sheets or clods obtained in the production process gives fairly wide grain-size distributions. By sieving out the dust and oversize grain, narrow grain-size ranges can be obtained fixed, but with simultaneous reduction of the production capacity. Oversize grain must be returned to the mills, and the dust component is usually added to the premix and therefore passes once more through the production plant. A reasonable grain size therefore usually comprises the range from 0.2 to 1.0 mm grain diameter. Such a range of grain sizes has a good

flowability and does not tend to demix, even during long-distance transport. Removing the very fine fractions on vibrating sieves is sometimes problematic because the very fine dust adheres strongly to the grains of molding compound, and because in the subsequent mixing processes the brittle granules rapidly form dust by abrasion. By careful control of the process, however, almost dust-free granules can be produced. Although these modern low-pollution granules are more convenient for the processor, the older commercial forms with a high dust content (up to 30 %) gave moldings with better mechanical properties and surface quality.

With coarser fillers, the upper limit of grain size is extended to ca. 8 mm, whereby the flowability deteriorates. If high-strength materials with good flowability are to be produced, special granulation processes are necessary, such as pelletizing or compression granulation. For thermoset molding compounds with high fiber content the latter is generally carried out on extruders, giving "sausage-like" granulates with diameters of 1 – 6 mm, depending on the filler.

Molding compounds with particularly coarse fillers, such as those produced by wet compounding of macerates (e.g., Type 74), are also supplied as briquettes, weighing up to ca. 1 kg. A special granulation method is used for the aminoplastic Types 131 and 152. These cellulose-filled molding compounds are usually produced in undyed form and are subsequently dyed in ball mills. This procedure is useful because of the variety of shades of color required for these molding materials. Very fine dust is formed in the ball mills and must subsequently be recompacted in, e.g., tabletting machines, pelletizers, extruders, or pan granulators. Depending on the method used, compaction may be followed by grinding and sieving.

Manufacturers. An extensive compilation of the manufacturers and processors of thermoset molding compounds appears in the journal *Kunststoffe*, usually in the February issue.

Some important manufacturers of thermoset molding materials in Europe are:

- Bakelite GmbH, Iserlohn Lemathe, Germany
- Phönix Gummiwerke AG, Hamburg, Germany
- Dr. F. Raschig GmbH, Ludwigshafen, Germany
- Resart Ihm AG, Mainz, Germany
- Süd-West Chemie GmbH, Neu-Ulm, Germany
- Perstorp, Sweden
- Vynckier, Belgium

4. Storage and Transport

Since the molding compounds discussed here cure on warming they should preferably be stored in cool rooms. The storage temperature depends on the type of material.

Phenolics and aminoplastics should preferably not be stored above room temperature. Phenolics based on novolac – hexamethylenetetramine (the majority) can be kept in this way for years. The storability of phenolics based on resols, and of aminoplastics is lower. Since these polycondensation molding compounds readily absorb or lose water, depending on the ambient humidity, the relative humidity of the store rooms also plays an important role. A relative humidity of ca. 50 % is recommended.

Packaging of molding compounds in multilayer paper sacks with polyethylene liners protects against the uptake or release of moisture for several months. Changes in humidity in phenolics and aminoplastics affect the flow – cure behavior of the molding compounds, in particular.

Polyester resin molding compounds also should be stored below room temperature. The storage life is then at least 6 months. Modern styrene-free, free-flowing polyester compounds achieve storabilities comparable to those of phenolics.

In earlier times epoxy resin molding compounds were stored in refrigerated rooms, and sometimes shipped in cooled vessels. However, for modern epoxy resin molding compounds this is no longer necessary.

Thermoset molding compounds are increasingly transported and stored in containers. This guarantees the exclusion of moisture and permits processing in closed systems on modern injection molding machines. The molding compound can thus be conveyed via suction-pneumatic or mechanical conveyor systems, without dust problems, into the feed hopper of the injection molding machine.

The containers range in capacity from 500 kg to ca. 2000 kg and can be made of metal, cardboard, or plastic. Cardboard containers are used as disposable packaging. They are less moisture-proof and more easily damaged. Containers made of steel sheet or aluminum have considerable weight when empty, and therefore cause additional costs for return freight. However, they are undoubtedly the safest packaging and protect the contents even under highly unfavorable weather conditions.

5. Properties

5.1. Uncured Molding Compounds

For the uncured molding compound the most important property is the processing behavior. The following properties are tested [4, 6]:

1) Flowability
2) Grain size (or grain-size distribution)
3) Bulk density
4) Filling factor
5) Flow – cure behavior

The *flowability* (DIN 53 492) of granular plastic is usually assessed in funnels of defined shape or with automatic metering devices. A simple method is determination of the angle of repose.

The *grain size* (DIN 53 477) is measured on sieving machines, the residues on the test sieves being weighed. The measured values can be evaluated either directly or by the Rosin – Rammler method, in which the measured values are plotted on a double-logarithmic scale. A straight line is obtained, whose slope allows the uniformity of the grain distribution to be inferred. An advantage of this method is that deviation of the curve from the straight line indicates a fault in the sieving plant.

The *bulk density* (DIN 53 468) is of importance for volumetric metering. First the weight of loose material that can be accommodated in 1000 mL is determined and then divided by the volume to give the bulk density. Since volume metering is often employed in the processing of thermoset molding compounds, the maintenance of the bulk density from delivery to delivery is very important.

The *filling factor* is the ratio of the relative density of the molded material to the bulk density of a molding compound. It plays a role when the transfer chamber of a mold is limited in size. Then, a certain minimum bulk density must be used.

The *flow – cure behavior* is the most important processing property of a thermosetting molding compound. Contrary to thermoplastics, not only does the viscosity of thermosets decrease on heating, it also rises again with the onset of curing (Fig. 4). The viscosity curve is thus U-shaped, the falling branch being determined by the physical process of heating, and the rising leg by the chemical curing reaction. The more steeply the left-hand branch falls, the more readily the molding compound softens. For compression molding, the softening behavior is the most important property of the thermoset molding compound. The middle part of the U-shaped curve is a measure of the lowest possible viscosity and determines the lowest possible processing pressure. The width of the curve and the steepness of the rising leg are measures of the curing rate.

Figure 4. Flow-cure behavior of thermoplastics (A) and of thermosets (B) on heating to processing temperature

There is no test method that covers the whole curve. Generally two complementary tests are employed.

In the plates method (Fig. 5) a defined amount of molding compound is pressed flat between two heated plates at a given pressure. The width or height of the "cake" is then used as a measure of the flowability. The drawback of this process is that the specific pressure changes continually during the deformation.

Figure 5. Testing of flow behavior by the plates method

In the beaker method (DIN 53 465, Fig. 6) a molding in the shape of a beaker is produced at a given pressure and a given temperature. The time from the lowering of the ram onto the material to complete sealing of the compression mold is measured. This "beaker time" is a measure of the softening and flow behavior of the material. In addition, the stiffness on demolding is tested. The beaker, still hot, is loaded on its top edge with a defined force (e.g., 10 N) and compressed.It undergoes a deformation that depends on the degree of cure. At a given curing time and curing temperature, the compression in millimeters is a measure of the stiffness on demolding. If several beakers with increasing curing time are tested, the curing rate of a molding material can be determined. In the American version of the beaker method (ASTM D-731) minimum pressure for the outflow of the beaker is measured. Here, therefore, several pressings are for time deter.

Figure 6. Testing of flow behavior by the beaker method

In the rod method (Fig. 7) a tablet of the material is pressed from a heated chamber under defined pressure into a heated flow channel. The length of the rod formed is a measure of the flowability. Recording the growth of the rod with time gives softening curves. If the tablet is left in the heated chamber for various lengths of time before it is pressed into the flow channel, and the length of the rod obtained is plotted against the time, curing curves are obtained. This Rossi – Peakes flow test is only suitable for short-fiber molding compounds. For coarse-structured materials, rods of larger diameter are used.

Figure 7. Testing of flow behavior by the rod method

A variation of the rod method is the spiral test, in which the rod is spirally wound, allowing long rods to be accommodated in a relatively small mold. These long rods are required for testing thermoset molding compounds that flow particularly readily. Thermosets of this kind, also known as low-pressure materials, are used in the electronics industry for encapsulating sensitive components. Epoxy resin molding materials in particular are tested by this method in EMMI spirals (EMMI: Epoxide Molding Material Institute).

In the kneader method (Fig. 8) the forces developed at the kneading blades when the molding compound is kneaded are measured (e.g., with a Brabender plastograph). If a defined amount of the molding material is introduced into the small heated kneader, the expenditure of energy at first falls on melting and then, as

Figure 8. Testing of flow behavior with a Brabender plastograph
a) Motor; b) Gearing; c) Motor kneader

curing begins, rises again. Finally the material becomes crumbly, and the expenditure of energy falls again. The quantity measured is the torque developed by the driving motor, which gives a U-shaped curve. However, this test does not measure the entire flow – cure behavior, since the material crumbles before it is completely cured.

The rotary viscometer or Kanavec method (Fig. 9) is the most precise test of flow – cure behavior. A test specimen resembling a bicycle hand-grip is molded in a special mold, and during the curing process the male mold is rotated slowly (e.g., 1 revolution in 20 min) relative to the mold cavity. The quantity measured is the torque required for uniform rotation or the shearing stress generated. This method records very accurately the lower part and the rising branch of the U-shaped viscosity curve of thermoset molding compounds.

Figure 9. Testing of flow behavior by the Kanavec Method

A special form of the test is the Philips method, in which a mushroom-shaped ram is pressed into a cylindrical mold cavity. The ram has slits, through which the molding compound can escape upwards during the deformation process. The quantity measured is the loss of material or the thickness of the cured residual material.

5.2. Cured Moldings

The properties of cured moldings are always a combination of the binder properties and the filler properties. A survey is provided in DIN 7708 for phenolics and aminoplastics, and in DIN 16 911 for unsaturated polyester resins.

Materials Based on Phenolic Resins. Phenolic resin molding compounds yield moldings with small susceptibility to cracking and small aftershrinkage (Table 3). They are mostly of low flammability, but generally have a low tracking resistance. They are not light stable, and slowly discolor under the influence of light. They are therefore manufactured only in black, brown, or muted red and green shades. Aminoplastics are fully light stable and can be supplied in light and colored shades.

Materials Based on Urea, Melamine, and Melamine – Phenolic Resins. These molded materials have particularly low flammability and, in combination with suitable fillers, exhibit very high tracking resistance (Table 4, see next page), especially in the case of melamine resins. However, both the urea – formaldehyde (UF) and melamine – formaldehyde (MF) aminoplastics have relatively high aftershrinkage values. In unfavorable cases this can lead to suscepti-

bility to cracking and to distortion at elevated temperatures.

The aminoplastic – phenophlastic (MP) molded materials (Types 180 – 183), as a result of the small proportion of plasticizing phenolic resin, behave more advantageously. With pale shades, however, only a very small proportion of phenolic resin is possible.

Materials Based on Polyester Resins. Polyester resin molding compounds (UP) have extremely small aftershrinkage (Table 5). They can be pale or colored and are light stable, resistant to tracking, and dimensionally stable. Thus they exhibit a combination of the advantageous properties of phenolics and aminoplastics, without their drawbacks. At first, UP materials were produced from styrene-containing unsaturated polyester resins with a relatively high proportion of glass fibers. Owing to their moist, fibrous structure, they were also known as "sauerkraut compounds". They yielded mold-

∗ Maximum values.

ings of relatively uneven structure and were therefore mainly used for engineering components.

Improved surface quality was achieved by so-called low-profile additives (thermoplastic additives), which made possible the use of UP molding materials for high-quality visible components.

The use of monomer-free solid UP resins was a further decisive breakthrough. With them, perfect surfaces without sink marks, such as are required for domestic appliances, can be made. Such UP molding materials are dry, free-flowing, and low-polluting and can be processed on conventional automatic machines like phenolics and aminoplastics. However, unlike the latter, the polyester resin molding materials do not cure by a polycondensation process but by polymerization. Since with this curing process no low-molecular condensation products such as water are split off, polyester moldings can be removed from the mold sooner and molded at lower pressures. The curing process is initiated by the addition of peroxides. The mold temperature necessary for the curing is adjusted to suit the peroxide used. An advantage of the polyester resins is that their synthesis from diols and diacids as well as the chain length between cross-links can be varied within a wide range. A further interesting property of styrene-containing polyester resins is that their viscosity is increased greatly by adding magnesium oxide. This enables the production of UP molding compounds that are resin-rich but still highly viscous. The production of prepregs (DIN 16 913) makes use of this effect (→ Reinforced Plastics, Chap. 3.9.).

Dry, free-flowing polyester resin molding compounds containing organic fibers (e.g., cellulose) instead of glass fibers have gained acceptance particularly in the domestic appliance sector.

Materials Based on Epoxy Resins. Epoxy resin molding (EP) were classified under DIN 16 912 (Types 870 – 872). However, this field is undergoing changes in the binders used, so that some older types have been withdrawn. However, DIN 16 912 enables a survey to be made of the basic properties of EP materials (Table 6). With these resins the number of possible combinations is even greater than with polyesters. Epoxy resins can be cured by three different methods: basically with diamines, acidically with diacids or acid anhydrides, and catalytically with Lewis acids. Epoxy resin molding compounds of the older Types 870 – 872 tend to yellow; therefore, only muted, dark colorations are possible. Hence they are used only for engineering components. Formerly, the storability of EP materials was poor, and cooled containers and cold rooms were necessary. Meanwhile, however, it has become possible to produce types with good storability and considerably improved light stability [7], although the light stability does not reach that of the UP molding compounds. The advantage of the epoxy resin molding compounds lies in their combination of good physical properties, freedom from overcuring, even at very high curing temperatures, and the very low processing shrinkage and aftershrinkage. Epoxy resin moldings therefore have a particularly low tendency to thermal stress cracking. Owing to their chemical composition they

Table 6. Properties of epoxy resin moldings (DIN 16 912) ∗

Type	Filler	Base resin	Density, g/cm^3, ca.	Bending strength, N/mm^2	Impact strength, kJ/m^2	Notch impact strength, kJ/m^2	Martens temperature, °C	Surface resistance, comparative figure	Water absorption, mg
870	inorganic granular stone powder	epoxy	1.9	50	5	1.5	110	12	30

∗ Minimum values, except for water absorption (maximum value).

have a very good resistance to water and chemicals.

In addition, epoxy resin moldings have the advantage of retaining their electrical properties even under unfavorable climatic conditions. They permit formulations that are processible at low pressure (low-pressure compounds). The adhesion to metallic inserts is very good.

Miscellaneous Binders. For particularly demanding electrical requirements, diallyl phthalate molding compounds are used, with a prepolymer from diallyl phthalate as binder. The fillers can be impregnated with the powdery prepolymer by the melt fusion process. Peroxides are suitable for curing, as with the UP resins. Molded materials on this basis have outstanding electrical values, especially in moist atmosphere, and meet U.S. Military Specifications, above all in aircraft construction.

Silicone resin molding compounds satisfy still higher electrical and thermal requirements. These materials play a certain part in electronics for sheathing semiconductors. They have a very high temperature stability, even over long periods of time, but are very expensive.

Cold molding compounds based on special phenolic resins have only limited storability. They have gained some commercial importance because they permit the manufacture tracking-resistant PF moldings. Cold molding compounds (DIN 7708, part 14) are compounded wet in kneaders and molded cold. The moldings are subsequently cured pressureless with stepwise increase of temperature over a fairly long period of time (up to several days). The surface quality and dimensional accuracy of such moldings do not, however, approach the high standards of conventional moldings.

Test Methods for Molded Materials. Most of the test methods used for testing molded materials are defined in DIN specifications. For thermoset plastics, the test specimens are produced by compression molding. This eliminates the filler-orientation effects which invariably occur in injection molding. Studies are available that allow the directional dependence of the properties of injection molded test specimens, to be estimated, especially the shrinkage behavior [8, 5].

The most important DIN test methods are:

Bending strength	DIN 53 452
Impact and notch impact strength	DIN 53 453
Compressive strength	DIN 53 454
Modulus of elasticity	DIN 53 457
Ball indentation hardness	DIN 53 456
Martens heat resistance	DIN 53 458
Linear expansion coefficient	DIN 53 752
Thermal conductivity	DIN 52 612
Incandescence resistance	DIN 53 459
Surface resistance	DIN 53 482
Electrical volume resistivity	DIN 53 482
Dielectric loss factor	DIN 53 483
Relative permittivity	DIN 53 483
Dielectric strength	DIN 53 481
Tracking resistance	DIN 53 480
Water absorption	DIN 53 495

In addition there is also a series of special test methods laid down by firms or associations, and test specifications for thermoset plastics from ISO, European Standards EN, and the UL (Underwriter's Laboratories).

Users' requirements for comparability of very different plastics have been generally accepted, which led to revision of DIN 7708. This began with a harmonization of the dimensions and production of the test specimen and was completed with the new edition of DIN 7708, part 8 (February 1992).

The new test specimen is of a multipurpose type, originally proposed for thermoplastics, and adapted to the special requirements for the processing of thermosets. Dyes for producing the test specimens by injection molding and compression molding have been developed, and comparisons made between the test values obtained and the previous values.

6. Processing and Aftertreatment

Thermoset molding compounds are hot molded and cured under pressure, sometimes with the addition of hardeners. The usual processes are compression molding, injection molding, transfer molding, injection – compression molding, and extrusion. For a detailed description of the processing of molding compounds to give cured moldings, see [4].

Moldings must generally be deflashed. This can be performed manually by filling, grinding, punching, sawing, abrasive blasting, or brushing. For small moldings or large numbers, mechanical processes are used, such as tumble deflashing, abrasive blasting, or brushing. Saw-

ing, milling, turning, and drilling are also possible [9]. Tools with carbide cutting edges are usually used. Detailed information on steel quality, cutting speed, and tool quality can be found in [9].

If necessary, the moldings can be polished with polishing wheels or in drums. Thermoset moldings can be joined by detachable joints (e.g., screw or clamp joints) or nondetachable joints such as rivets and adhesive bonds [10].

Thermoset moldings are sometimes finished by painting, flocking, hot-embossing, printing, or metallizing by electrodeposition or vacuum deposition.

7. Uses

The main applications for moldings made from thermoset molding compounds are electrical engineering, domestic appliances, mechanical engineering, the automotive industry, and the sanitary sector. Thermoset molding materials also have versatile uses as bottle seals, in precision engineering, and in office machine manufacture. Typical moldings in the electrical engineering sector are collectors for electric motors, slip rings, contacts, strip terminals, distributor box cases, switches, plugs, and other connectors. Collectors also play a major role in the automotive industry, as well as ignition distributors, spark plug sockets, control pistons for power brakes, bushes, and axial face seals. In the household sector, thermoset moldings are used for high-quality camping ware, ashtrays, handles for irons, pot and pan handles, grill and toaster components, lamps, and cutlery. In the sanitary sector, high-quality toilet fittings are manufactured in many colors from thermoset molding compounds. They are used for a great variety of cosmetic containers (including metallized ones). In mechanical engineering, they are suitable for highly stressed bearings, including self-lubricating bearings, and for coverings, rollers, reels and operating controls.

8. Economic Aspects

The "thermosets" discussed here (thermoset molding compounds) constitute only a narrow area of the thermosetting plastics. They contain 20 – 60 % of thermosetting binders, but such binders are also constituents of a wide variety of other products. Production of curable free-flowing molding compounds is summarized in Table 7.

Table 7. Production of curable, free-flowing molding compounds

Region	Production, 10^3 t			
	1979	1982	1985	1988
Federal Republic of Germany *	58	55	59	60
Western Europe	210	190	215	207
United States	189	115	135	133
Japan	120	115	114	103

* Without urea molding materials, which are no longer produced in Germany.

For the phenolic resins, which make up ca. 2 % of foundry molding compounds and ca. 60 % of electrical laminates, a total production volume of material for the Federal Republic of Germany in 1988 of almost 3×10^6 t can be estimated [11]. The production of thermoset molding compounds based on phenolic resin, on the other hand, is much lower, Table 8 [12].

Table 8. Production of phenolic molding compounds

Region	Production, 10^3 t				
	1987	1988	1989	1990	1991
Japan	59.2	64.9	67.3	65.2	64.8
Korea	5.0	5.4	5.8	5.8	6.0
South-East Asia	16.2	17.8	25.0	26.0	28.0

Germany *	29.0	31.0	32.0	32.0	31.5

* Included in data of Western Europe.

Market growth for thermoset molding compounds is estimated at 3 – 4 % for the next few years. In automobile manufacture even 6 – 7 % may be reached. Here the thermosets compete mainly with metals. Quantitatively, the largest fields of application are electrical engineering, followed by domestic appliances and tableware, and sanitary products. These considerations do not include the large field of polyester dough molding compounds (bulk molding compounds, BMC) and prepregs (sheet molding compounds, SMC).

9. Environmental Protection and Recycling [13]

Safety data sheets (DIN 52 900) are available for all thermoset molding compounds. They give information on storage and handling, transport, fire protection, toxicology, ecology, waste disposal, etc.

Phenolic moldings that contain $> 1\,\%$ free phenol must be labelled as harmful (X_n). However, by the 1970s manufacturers had already undercut this 1 % limit by using low-phenol resins. Most phenolic molding compounds therefore do not require such labelling. According to all transport regulations, molding compounds are not deemed to be hazardous materials.

In connection with processing, further questions arise such as which gases and vapors are formed, and in what amounts? For phenolic molding compounds, extensive studies on this subject are available. During processing, phenol, formaldehyde, and ammonia are released, in addition to water vapor. The quantities have been determined by using an enclosed mold, extracting the gases, and absorbing them in appropriate solutions. The following approximate values were obtained:

- Phenol, ca. 5 mg per kg molding compound
- Formaldehyde, ca. 2 – 4 mg per kg molding compound
- Ammonia, ca. 20 – 40 mg per kg molding compound

The MAK values for these substances :

- Phenol 5 ppm (19 mg/m^3)
- Formaldehyde, 0.5 ppm (0.6 mg/m^3)
- Ammonia, 50 ppm (35 mg/m^3)

can be maintained by using extraction hoods.

During processing of aminoplastics, formaldehyde quantities of up to ca. 25 mg/m^3 have been observed, and demands on the extraction equipment are therefore greater.

Thermoset molding compounds based on phenolic resin, melamine resin, and urea resins contain as binder polycondensation products produced using formaldehyde. However, owing to polycondensation formaldehyde is not present in the free form. Curing converts the resin molecules via reactive centers derived from formaldehyde into an almost inert network, which gives the molded materials their resistance to temperature and aggressive media. With correct curing, the regeneration of formaldehyde in the molding is possible only to a minor extent in the case of the aminoplastic molding compounds (UF, MF and MP). However, it is observed only under extreme thermal or hydrolytic conditions. In moldings based on phenolic resin, such a release of formaldehyde is practically immeasurable.

No formaldehyde is used in the synthesis of unsaturated polyester resins. For special applications, polyester molding compounds are modified with up to 5 % melamine resin. In these cases small quantities of formaldehyde can escape during the processing.

During the processing of styrene-containing unsaturated polyester dough molding compounds, styrene may be released. Meeting the MAK value for styrene of 20 ppm (85 mg/m^3) requires elaborate ventilation systems. Producers of such UP molding compounds are therefore attempting to reduce the styrene content of their products.

A few years ago asbestos was still a popular reinforcing fiber for thermosets. Although the fibers are enveloped by resin in the process, in compounding and aftertreatment of the moldings exposure of the fibers cannot be avoided. Such asbestos fibers are classified as carcinogenic in certain geometries (particles with a length of $> 5\,\mu$m, and a diameter of $< 3\,\mu$m with a length-to-diameter ratio $> 3:1$). Substitutes have since been found and new asbestos-containing molding materials are no longer marketed. The Bakelite company, for example, ceased production of asbestos-containing molding compound at the beginning of 1991.

Recycling of thermoset molding compounds was carried out as early as the 1930s, but was not economic at that time, since the wastes had to be very finely ground to avoid surface defects in the new moldings. There was also a risk of entraining impurities. For controlled, quality-assured moldings in Germany the addition of reground material is only allowed if the processor undertakes the inspection necessary to safeguard quality.

As early as the 1970s, studies were carried out worldwide to facilitate the addition of reground material. The conclusion was that the addition of

10 – 20 % of reground material is possible without significantly impairing the test values.

A similar particle recycling process is used for sheet molding compounds. Raw material manufacturers and processors have established a company for this purpose (Ercom, Karlsruhe).

The problem of damage to thermoplastics on recycling does not occur with thermosets, since the reground material is used as a filler. In the finely ground state, this reground material is a particularly high-quality filler since it is impregnated.

The regenerate can be added either batchwise in mixing vessels or continuously in injection molding machines. The particle size of the regenerate should be ca. 0.1 – 0.4 mm. Too coarsely ground material leads to surface and textural defects.

Incineration. Since most thermoset molding compounds are free of halogens, disposal by incineration is also possible. The calorific values of such wastes of 12500 – 21000 kJ/kg are relatively high. However, thermoset wastes are not accepted by all refuse incineration plants. It is occasionally possible to use them as additives in cement manufacture to economize on oil and coal.

Dumping. Because of their insolubility, cured molded materials can be dumped on landfills for domestic waste. Uncured wastes are regarded as pollutants.

In Germany an active environmental study group for thermosets has existed for several years [14].

A comprehensive survey of the problems of plastics recycling is given in [15].

1. Preparation of Thin Films

1.1. Chemical Vapor Deposition Processes

Chemical vapor deposition (CVD) produces layers from the gas phase with thicknesses in the range ca 0.1 – 10 µm, by means of a chemical reaction. Typical pressure ranges are different from those used in physical vapor deposition (< 1 hPa); ca 1 – 50 hPa for low-pressure CVD (LPCVD), 50 to < 1000 hPa for medium-pressure CVD, and atmospheric pressure for atmospheric CVD (ACVD) [1–8]. Accordingly, the Knudsen number λ/d (the ratio of the mean free path of molecules in the gas phase to a typical reactor dimension) is small, and diffusion and convection processes are the main transport mechanisms. Reynolds numbers are in the range 1 – 1000, so laminar gas flow is the normal flow mode and buoyancy effects are important, especially at higher pressure [7].

In contrast to chemical transport processes [9], CVD is an open system with a gas inlet and outlet. The equipment (Fig. 1) has the following main parts: a gasification system (a, b, c, j), a chemical reactor with volume of the order of cm^3 or m^3, which contains the samples or workpieces to be coated (d, e, f), and an exhaust system for the reacted gas (g, h, i). Precursor compounds can be inorganic (e.g., halides, hydrides, carbonyls) or organic (alkyls, β-diketonates, alkoxides, or organometallics [10, 11]). Almost all compounds can be deposited by CVD, provided the material can be dissolved in the gas phase. Usually, the possibility of depositing material from a gas mixture and the expected phase composition can be calculated by thermodynamic equilibrium calculations, minimizing the Gibbs free energy. These estimates are especially suitable for CVD processes at high deposition temperatures (e.g., SiC deposition at ca. 1000 °C [12]). At low temperature, kinetic effects are often important, and the deposition of metastable phases (e.g., amorphous SiO_2) is possible.

The structure of the coating is the result of several steps: adsorption – desorption processes, surface reactions, surface diffusion, nucleation, growth of the critical nuclei, layer formation, and aging processes in the layer during deposition. The result ist often the formation of preferred orientations of the deposited layer on crystalline and amorphous substrates, depending on the deposition conditions. On monocrystalline sub-

strates, epitaxy is possible if the lattice misfit is not too large [13].

Figure 1. CVD system for deposition on tools (e.g., TiN, TiC)

There are a number of methods to activate the chemical reactions necessary for deposition. These methods are described in the following.

Thermal CVD. The surface or homogeneous reactions necessary for layer formation can be thermally activated (thermal or conventional CVD) by heating the reactor, including the samples (hot-wall reactor, Fig. 1) or by heating the samples only (cold-wall processes) to the deposition temperature T_{d} (Table 1). These processes have the "ideal" temperature dependence shown in Figure 2. At medium temperature, in the so-called transport-controlled regime, transport in the gas phase determines the deposition rate, and the temperature dependence is very smooth, proportional to T^{ν} with $\nu = 0.7 - 1.0$. This range can be used only for deposition on simple geometries, because the deposition depends critically on gas flow conditions. Deposition rates are determined by the concentration of precursor molecules in the gas phase and by the gas flow. In stagnation flow reactors, deposition rates up to 100 µm/min can be reached, as shown for tungsten deposition with a precursor content in the hydrogen gas phase of ca. 30 % WF_6 [15].

Figure 2. Temperature dependence of an "ideal" CVD process

At low temperature, the deposition rate is given by an Arrhenius law:

$$\dot{s} = k \exp(-E/RT) \tag{1}$$

where k is a constant, E is the activation energy, and R the gas constant. In surface reactions, T is equal to the deposition temperature T_{d}. If the rate-determining step is in the gas phase, it is dif-

Table 1. Examples of thermal CVD processes

Deposited material	Type of reaction	Reaction	Deposition temperature, °C	Activation energy, kJ/mol	Ref.
W	pyrolysis	$WCl_6 \rightarrow W + \ldots$	>1000		
W	reduction	$WCl_6 + 3\,H_2 \rightarrow W + \ldots$	>800	627	[14]

* dpm = Dipivaloyl methanoat

ficult to determine the reaction temperature if the reactor is not isothermal. Typical activation energies are given in Table 1. At high temperature, the deposition rate often decreases because homogeneous reactions and nucleation in the gas phase reduce transport of precursor molecules to the surface. Very often the deposition characteristics is much more complicated than shown in Figure 2. A more detailed description of the dependence of deposition on pressure, temperature, gas composition, and gas flow is then possible by the methods of chemical kinetics and the theory of catalysis including fluid dynamics. The kinetically controlled range shown in Figure 2 can also be used for the deposition inside porous materials. This process is called chemical vapor infiltration (CVI) [19,20]. Thus the temperature dependence is often more complicated than shown in Figure 2.

The activation of the chemical reaction at the surface can also be achieved by laser irradiation [21]. In this case, localized deposition with lateral dimensions down to a few micrometers is possible. This laser CVD process can be mainly thermal or mainly photochemical (photo CVD), and allows patterning of surfaces by laser-direct write. The fabrication of three-dimensional microobjects by laser CVD has been demonstrated [22].

In recent years there has been interest in the development of efficient lamps to replace the cost-intensive lasers. The intense ultraviolet (UV) light is generated on these devices using dielectric barrier dischargers to form excimer molecules of rare gases and rare gase halides [23]. This has provided the oportunity for inexpensive large area photo CVD [24].

Practical deposition rates (0.1 – 1 μm/min) are mostly a compromise between the coating structure and the throwing power (the ability to produce layers of constant thickness on the surface of the workpiece). Thermal CVD processes are used industrially for the production of hard coatings (TiC, TiN, Al_2O_3), and in the electronics industry (Si, SiO_2, Si_3N_4, III – V compounds).

Plasma CVD. Very often the deposition temperature of conventional CVD is too high; deposition methods have been developed to decrease the deposition temperature, e.g., plasma-activated deposition processes (PACVD), also called plasma-enhanced CVD (PECVD). A plasma is an electrically neutral gas in which neutral species, ions, and electrons are all present. Plasmas are ignited by d.c. or a.c. in the frequency range MHz to GHz. ln d.c. (continuous or pulsed) discharges, the sample is the cathode and the discharge is ignited between the cathode and the anode. The cathode surface is coated and at the same time bombarded with positive ions with energy in the range of a few hundred volts, and current density 1 – 10 mA/cm^2. If the sample to be coated is insulating, an a.c. discharge is necessary to avoid charging effects. The different mobilities of ions and electrons produce a space-charge layer on the electrodes, with a potential drop similar to that in a d.c. plasma. The voltage can be further increased by changing the ratio of the electrode areas, smaller areas being associated with higher voltages (approximately proportional to $(A_1/A_2)^\nu$, where A_1 and A_2 are the areas of the the electrodes, and $\nu = 1-4$ [6], [25]. In plasmas used for CVD, the ratio of charged to neutral species can be as low as $10^{-6} - 10^{-5}$ [6,26] (weakly ionized plasmas). The total pressure is $10 - 10^3$ Pa. This low pressure leads to few collisions in the gas phase before species reach the walls or recombine. Therefore, no complete temperature equilibration of neutral species, ions, and electrons is formed. Neutral species and ions have temperatures in the range $kT = 0.1$ eV (where k is the Boltzmann constant, 0.1 eV = 1160 K); electron temperatures are in the range 1 – 10 eV. The role of the plasma can be twofold:

1) To change the gas phase composition and thus change the reaction system by formation of intermediates, radicals, excited molecules, and ions. Plasmas for this application can also be produced remote from the sample position (Fig. 3 A).
2) To modify the gas phase and deposition conditions. This is achieved by ignition of the gas discharge directly above the deposition surface (Fig. 3 B). Ion bombardment through the space-charge layer changes the surface processes and hence the structure of the coating, usually improving adhesion to the substrate.

Plasma CVD processes are used for the production of hard coatings on steels [26] and in the electronics industry (Si_3N_4).

Figure 3. Basic configurations of plasma reactors for CVD
A) Remote plasma reactor (inductively coupled); B) Parallel-plate reactor (capacitively coupled)

1.2. Plasma Polymerization

Plasma polymerization refers to the formation of polymeric films on surfaces in proximity to a low-pressure glow discharge in an organic or organometallic vapor. Among the unique properties of these films are: controlled thickness up to ca. 2 µm, good adhesion to a variety of substrates, and variable physical properties such as hardness. The useful characteristics of such films has led to their widespread use in applications as diverse as protective coatings and osmotic membranes. Some of the features of plasma polymerization are similar to those found in plasma-enhanced chemical vapor deposition (PECVD). Several plasma parameters are known to influence the polymerization process, including pressure, flow rate, power and frequency of the discharge, and reactor geometry.

A variety of reactor geometries have been used, including those with internal or external electrodes. Reactors with internal electrodes usually have a parallel plate design in which one electrode is grounded (onto which the substrate is placed) and the other is fed with capacitively coupled radiofrequency (r.f.) power. Tubular reactors are often inductively coupled.

A typical bell jar reactor with horizontal, parallel plate electrodes is shown in Figure 4. It has been used [27] to prepare protective films of fluorinated polymers from tetrafluoroethylene (TFE) and chlorotrifluoroethylene (CTFE) monomers. Plasma reactors must have good vacuum integrity; in this example it was better than 1 Pa. The pressure in the operating reactor was ca. 10 Pa. Typical deposition rates over a 5-cm diameter substrate were $7.9\times10^{-6}\,\mathrm{g\,cm^{-2}\,min^{-1}}$ ($48\,\mathrm{nm\,min^{-1}}$) with 20 W r.f. power, 13 Pa TFE, and 13 Pa argon. Deposition time for a 1-µm coating on NaCl substrate was ca. 40 min.

Figure 4. A parallel plate capacitively coupled plasma reactor [27]
a) Ground electrode; b) Support pedestal; c) Optical crystal; d) Hot electrode, e) Plasma

The control and measurement of pressure in a reactive plasma presents several problems. The pressure in the reactor can change significantly when the discharge is turned on, even at constant flow rate, owing to changes in the concentration and nature of the plasma species. The ideal device for measuring the pressure in the plasma must be immune from the electrical effects of the

plasma, and not disturb the plasma chemistry. A pressure transducer which is independent of the nature of the plasma species is usually selected. At constant flow rate and current density, the deposition rate increases linearly up to some limiting pressure. Maximum reactor pressures which have been used are ca. 500 Pa, but pressures below 250 Pa are usually employed.

Closely allied to the gas pressure is the flow rate F. The dependence of deposition rate on flow rate at constant pressure is as follows for ethane plasma polymerization. At high flow rates deposition tends to decrease with increasing flow rate, owing to decreasing residence time. Conversely, the longer residence times at low flow rates enable more of the monomer to react, and under these conditions deposition rate increases with flow rate. While this general behavior is repeated at different pressures, an increase in pressure leads to a decrease in deposition rate, owing to a lower in electron density [28].

Increasing the power density increases the deposition rate, as might be expected from the increased electron density. However, the plasma chemistry also changes which directly affects the rate of polymerization. Power dissipation depends uniquely on the reactor geometry and on the monomer under study.

To facilitate comparisons of one plasma with another Yasuda [29] has used a composite parameter W/FM, where M is the molecular mass of the monomer. The relevant dimensions are $(W/FM)\times 1.34\times 10^9$ J/kg, where W is the discharge power in Watts and F is in cm^3 (STP)/min. The most useful form of this parameter is at the critical power value W_c, defined as the power required to fill the reactor with the glow discharge. Above this power level, polymerization is independent of power and the pressure remains constant as the power is increased. The slope of plots of W_c/FM versus flow rate are approximately the same for different monomers containing the same functional group(s). The slope is highest for saturated hydrocarbons and W_c/FM is almost independent of flow rate for compounds with triple bonds or aromatic structure. The slope correlates with the quantity of H_2 produced in the plasma and is highest in the degradation of noncyclic saturated hydrocarbons. This has led to general classification [29] of hydrocarbons into three categories: compounds containing triple bonds in addition to aromatic structure; compounds containing double bonds and/or cyclic structure; noncyclic saturated hydrocarbons. This classification assumes unchanged reactor geometry.

Plasma polymerization discharges have been operated from d.c. to microwave frequencies (2.45 GHz). Probably the most commonly used frequency is 13.56 MHz. The disadvantage of d.c. plasmas is that extensive polymerization at the electrodes changes the discharge conditions. At high frequencies (13.56 MHz) the energetic charged species in the plasma are contained within the plasma itself. Polymer films which might be sensitive to highly energetic species are therefore best formed at high radiofrequencies.

The mechanism of plasma polymerization is not fully understood, but includes both homogeneous and heterogeneous reactions. A characteristic of plasma polymers is the presence of large concentrations of free radicals. This implies that free radicals are important in the polymerization process. More conventional polymerizations do not involve free radicals, which are normally quenched in the termination step. A free radical mechanism which explains the preponderance of these species is the rapid step growth principle. In RSGP, mono- or biradicals generated in the plasma can add to further monomer or other plasma molecules to form a new radical species, which can itself add further monomer or, if inactive, can be reactivated in the plasma and reenter the cycle [29]. In this scheme no distinction is made between gas phase or surface reactions.

Unlike conventional condensed-phase polymerization, which requires the monomer to contain one or more unsaturated functional groups, no such restriction applies to plasma polymerization and almost any organic molecule with a vapor pressure of a few hundred Pascals is amenable to this treatment. Monomers used include hydrocarbons, fluorocarbons, silane and other silicon compounds (siloxanes and silazines), and organometallic species.

1.3. Physical Vapor Deposition (PVD) Processes

The basic PVD processes fall into two general categories: sputtering and evaporation. The application of PVD techniques ranges from

Table 2. Classification of PVD processes

	Metals/alloys		Compounds	
Process	Basic	Hybrid	Basic	Hybrid
Conventional	evaporation deposition sputter deposition	ion plating sputter ion plating	direct evaporation direct sputtering	
Plasma-assisted (PAPVD)			activated reactive evaporation (ARE) reactive sputtering (RS)	reactive ion plating (RIP) biased RS (BRS)

decorative to high-temperature superconducting films. The thickness of the deposits can vary from 10^{-10} to 10^{-3} m. Very high deposition rates (25 µm/s) have been achieved with the advent of electron-beam-heated sources. A very large number of inorganic materials – metals, alloys, compounds, and mixtures as well as some organic materials – can be deposited by PVD technologies. "Ion plating" is a hybrid PVD process, i.e., an atomic film deposition process in which the substrate surface and/or the depositing film is subjected to a flux of high-energy particles sufficient to cause changes in the interfacial region between the film and the substrate, as well as in the properties of the deposited film compared with a nonbombarded film. These changes may be in the adhesion of the film to the substrate, film morphology, density, or stress. The source of the depositing species can be evaporation, sputtering, gases, or vapors (Table 2).

1.3.1. Sputter Deposition

Sputtering (Fig. 5) is momentum transfer from an indirect energetic projectile, such as an ion, to a solid or liquid target, resulting in the ejection of surface atoms or molecules. The target and the substrate are placed in the vacuum chamber and evacuated to a pressure of 10^{-2} – 10^{-5} Pa. The target (cathode) is connected to a negative voltage supply and the substrate generally faces the target. A glow discharge is initiated after an inert gas (usually argon) is introduced into the evacuated chamber. Typical working pressure is 2.5 – 20 Pa.

Planar Diode Glow Discharge Sputter Deposition. This is the simplest sputtering system, consisting of the cathode (target) and anode facing each other. The substrates are placed on the anode. The target, which is usually water cooled, performs two functions: as the source of coating material and as the electrode sustaining the glow discharge. The distance between cathode and anode is usually ca. 5 – 10 cm.

Figure 5. The sputter deposition process
a) Power supply; b) Cathode (target); c) Ion; d) Substrate; e) Plasma

The deposition rate is mainly determined by the power density at the target surface, size of the erosion area, source – substrate distance, source material, and working gas pressure. Some of these factors are interrelated, e.g., pressure and power density; optimal operation is obtained by controlling the parameters to get the maximum power flux which can be applied to the target without causing cracking, sublimation, or melting. The maximum power limit can be increased if the cooling rate of the target is increased by designing the coolant flow channels properly and improving the thermal conductance between the target and the target backing plate.

Even though planar diode glow discharge sputter deposition techniques are widely used, owing to their simplicity and the relative ease of fabrication of targets for a wide range of mate-

rials, they have several disadvantages: low deposition rate, substrate heating due to the bombardment of high-energy particles, and relatively small deposition surface areas.

Magnetron Sputter Deposition. By appyling magnetic fields to the diode sputtering process, the ionization efficiency can be greatly increased. In the magnetron sputter deposition process, an applied magnetic field parallel to the cathode surface forms electron traps and restricts the primary electron motion to the vicinity of the cathode. The magnetic field strength is of the order of 10^{-2} T and therefore itcan influence the plasma electrons, but not the ions. The electrons trapped on a given field line can advance across the magnetic field to the anode or walls via collisions (mostly with gas atoms). Therefore, their chances of being lost to the walls or anode without collisions are very small. Because of the higher efficiency of this ionization mechanism, the process can be operated at ca. 0.15 Pa with high current densities at low voltages, thus providing high sputtering rates.

There are several configurations of the magnetron sputter deposition technology. Figures 6, 7, 8 show the cylindrical magnetron, the planar magnetron, and the S-gun magnetron. The cylindrical magnetron is very useful to prepare uniform coatings over large areas, since long cathodes are employed. Furthermore, the cylindrical hollow magnetron technique is effective for coating complex-shaped objects. The cylindrical post magnetron can be used to avoid substrate bombardment by energetic particles, thus preventing heating of the substrate. Metallic and dielectric films can be deposited at higher deposition rates by planar magnetron sputtering than by diode sputtering. To deposit films on thermally sensitive substrates, such as electronic devices, the S-gun magnetron can be used, since this technique allows good isolation of the substrate from the plasma.

The balanced magnetron was developed primarily for metallization in microelectronic applications where electron/ion bombardment of the growing film is to be avoided. However, for metallurgical applications, ion bombardment of the film is desirable for the changes it produces in its structure and properties. Often, a separate ion gun is incorporated into the system to ion bombard the growing film. The development of the unbalanced magnetron has resulted in a practical way to carry out ion bombardment without the extra ion gun. Figure 9 shows the balanced and unbalanced magnetrons. The latter incorporates a controlled leak into the magnetic trap, permitting magnetic field lines as well as elec-

Figure 6. A cylindrical magnetron sputtering source

Figure 9. A) Balanced magnetron; B) Unbalanced magnetron

trons and ions to stream toward the substrate. A plasma is thus present near the negatively biased substrate from which positive ions can bombard the growing film.

Another variation is ion beam sputtering where ions of controlled energy from an ion source impinge on a target. The advantages are excellent adhesion; a resulting high-purity deposit because of the low operational pressure (ca. 0.015 Pa); and very low substrate heating effects since the substrate is not in contact with the plasma, as is the case for diode sputtering. If a second ion source is used to ion bombard the film, the process is called dual ion beam sputtering or ion-beam-assisted deposition. Optionally, an evaporation source can be used instead of the sputtering source to generate the vapor species.

Radiofrequency Sputter Deposition. Deposition can be performed at considerably lower pressures, e.g., 0.5 – 2 Pa, in r.f. sputtering compared with the planar d.c. discharge, since electrons oscillating at high frequency can obtain sufficient energy to cause ionizing collisions, and the number of electrons lost (without collisions) can be reduced.

Radiofrequency sputtering is widely used to deposit various kinds of conducting, semiconducting, or insulating coatings despite the complexity of the r.f. power source. This technique can also be applied to magnetron sputtering sources.

1.3.2. Evaporation Deposition

In the evaporation process, vapors are produced from a material located in a source which is heated by various methods (Fig. 10). The system consists of an electron-beam-heated evaporation source to vaporize the desired material. The substrates are located at an appropriate distance, facing the evaporation source. Resistance, induction, cathodic and anodic arc, electron beam, or lasers are the possible heart sources. The substrate can be heated and/or biased to the desired potential with a d.c./r.f. power supply.

Figure 10. Evaporation/deposition process with an electron beam source
a) Separator plate; b) Substrate(s); c) Electron beam gun; d) Ingot rod; e) Molten pool; f) Vacuum chamber

Evaporation is carried out in vacuum at 10^{-3} – 10^{-8} Pa. In this pressure range, the mean free path is very large ($5\times10^2 - 10^7$ cm) compared with the source – substrate distance. Hence the evaporated atoms essentially undergo collisionless, line-of-sight transport prior to condensation on the substrate, thus leading to thickness buildup directly above the source and decreasing steeply away from it. At a source – substrate distance of 20 cm, the vapor pressure should be ca. 1.5 Pa in order to get reasonable deposition rates (ca. 0.1 μm/min). The source temperature should be adjusted to give this vapor pressure. Specialized evaporation techniques include flash evaporation, laser or electron beam ablation, cathodic arc evaporation (including filtered arc), and anodic arc evaporation.

In the flash evaporation process, pellets of alloy are dropped onto a very hot strip and are vaporized completely, thus maintaining the composition of the alloy in the deposit. It works very well for elements with high vapor pressures. A newer version of flash evaporation is pulsed laser or electron beam ablation where a high energy pulse vaporizes a small chunk of the target material, be it alloy or compound, thus retaining target composition in the deposit.

Cathodic arc evaporation which evaporates small volumes of the cathode (target) may also be used. However, the problem of droplet ejection from the target causing major flaws in the deposited film precludes the application of this process for thin film deposition. One way around the droplet problem is the use of a filtered arc where the ion stream from the cathodic arc plume is extracted by an electromagnetic field and the ions are condensed to deposit a film.

The anodic arc is similar to the cathodic arc except that the anode material evaporates. There is no particulate emission with the anodic arc process. It is as yet a laboratory-scale process.

1.3.3. Deposition of Metals, Alloys, and Compounds

The great versatility of the PVD processes is their ability to deposit a very large number of materials, including metals, alloys, semiconductors, superconductors, polymers, and to fabricate composites of various types (particulate, fibrous, or laminate).

Single-Element Deposition. This can be carried out by evaporation or sputter deposition processes. The deposition rate depends on the process and process parameters.

Alloy Deposition. Alloys consist of two or more components, which have different vapor pressures and hence different evaporation rates. As a result, the composition of the vapor phase and the deposit are constantly varying. The following methods have been used to obtain alloy films with stoichiometry close to the source composition by evaporation-based techniques.

1) Co-evaporation or co-sputtering using multiple sources: this technique involves simultaneous co-evaporation of the constitutive elements of the alloy. The composition of the deposited film is controlled by adjusting the evaporation/sputtering rate of the respective elements. In elaborate systems, separate deposition rate monitors are used with feedback networks to control the deposition rate from each source independently.
2) Evaporation from a single source: this technique involves evaporation of an alloy using a rod-fed electron beam source. Evaporation operates under steady-state conditions where the composition and volume of the liquid pool on the top of a solid rod are kept constant [30].
3) Flash evaporation: in this process, pellets of the alloy are dropped onto a very hot strip and are vaporized completely, thus maintaining the composition of the alloy in the deposit. It works very well for elements with high vapor pressure.
4) Sputter deposition from an alloy target.
5) Sputter deposition from a segmented target where the segments consist of each of the two components of the alloy and the ratio in the target of each element is inversely proportional to their sputtering yields.
6) Laser ablation from an alloy target.

Deposition of Compounds. Deposition of compounds can be performed in two ways: direct evaporation/sputtering of a compound target, where the composition of the target is the same as that of the compound to be deposited; and reactive evaporation, where the elements of the compound are evaporated/sputtered and re-

act with the reactive gas to form the compound [30,31].

1.4. Thin Film Growth by Molecular Beam Epitaxy (MBE)

1.4.1. Introduction [32–35]

Film growth by molecular beam epitaxy (MBE) is based on the formation of thermal, neutral, collision-free molecular (or atomic) beams which interact under ultra-high-vacuum (UHV) conditions with a heated single crystal substrate to form a thin epitaxial film. The beams are formed by effusion from Knudsen sources and the condition for molecular flow is that the mean free path of the atoms or molecules of the beam material contained in the source is greater than the diameter of the effusion orifice. Beams can be formed from elements or compounds, which may be solid, liquid, or gaseous at room temperature, and the design of the Knudsen source is critically dependent on the state of matter involved. It will also influence the pumping system used to achieve UHV.

MBE has been used to prepare films of a wide range of materials, including metals and alloys, semiconductors, superconductors (especially high critical temperature oxides), alkali halides, and other insulators, but by far the most important application is to semiconductor films, with some emphasis on III – V compounds and alloys.

The major advantage of MBE over other methods of thin film formation is that the growth processes can be controlled at the atomic level. This is achieved by the application of a range of in situ diagnostic techniques which can operate in the UHV environment.

1.4.2. The Configuration of MBE Growth Systems

The essential elements of an MBE system are illustrated in Figure 11. It comprises a group of Knudsen cells whose detailed design depends on the nature and state of the source material, a heated stage on which the substrate can be mounted, and a mechanical shutter interposed between each source and the substrate, whose function is to intercept the beam and effectively provide a switching capability. All components are contained within a UHV chamber.

Figure 11. The basic arrangement of an MBE system
a) Monocrystal substrate; b) Ultrahigh vacuum chamber; c) Shutters; d) Knudsen sources (effusion cells)

Despite this apparent simplicity, implementation of the process requires a complex system, as illustrated in Figure 12. The important components are:

1) The UHV growth chamber, with associated pumping facilities
2) A vacuum interlock arrangement which enables substrates to be inserted and removed from the growth chamber without breaking the vacuum
3) A heated, rotatable substrate holder
4) A set of effusion cells and shutters, the operation of which is computer controlled

Process Environment. In general, systems are constructed from stainless steel, but all components should be capable of withstanding bake-out to 200 °C for outgassing. To achieve a base pressure in the growth chamber $< 10^{-8}$ Pa, the primary pumping for solid source systems is usually provided by a combination of sorption and ion pumps, perhaps with additional Ti sublimation and closed-cycle He cryopumps. Where a high gas throughput is involved, which is the case with gaseous or volatile liquid sources, trapped oil diffusion pumps, or more usually turbomolecular pumps are used instead of ion pumping. Secondary pumping takes the form of liquid-nitrogen-cooled cryopanels surrounding as much of the growth environment as possible and is used in all systems except those in which a toxic or pyrophoric condensible (at > 77 K) source gas is involved (e.g., SiH_4).

Figure 12. A solid source MBE system (VG Semicon, Fisons Instruments)

Vacuum Interlock and Substrate Preparation Chamber. It is critical that UHV conditions are maintained in the growth chamber as substrates are introduced and removed. A vacuum interlock system is therefore used in which the substrates are mounted on a movable holder, transferred from an entry lock into a preparation chamber, and finally into the growth chamber via a series of gate valves. The preparation chamber is used for the initial cleaning of the substrate surface, the final stage being carried out in the growth chamber. It is important that the substrate surface is clean at the atomic level and this is usually achieved by ex situ etching and in situ high-temperature treatment to desorb impurities, especially oxides.

Substrate Holder. Semiconductor substrates are typically circular wafers ca. 75–100 mm diameter and 0.25 mm thick. The function of the substrate holder is to provide a carriage for the wafers and to heat them uniformly. Growth temperatures are very dependent on materials, but are typically in the range 200–700 °C, most usually 500–700 °C. The holder is usually constructed from a refractory material block (most frequently Mo) heated by resistance or radiation from behind. In addition it must be capable of rotation within the UHV growth chamber at a speed comparable to the rate of growth of a monolayer of material, typically 1 s, so the rotation speed is ca. 1 Hz. The incident beams are neutral, and even with collimation they are necessarily divergent, so uniformity of thickness and composition over a reasonable area ($> 1\,\mathrm{cm}^2$) can be achieved only with substrate rotation. Substrate temperatures are usually measured with a calibrated optical pyrometer, but a thermocouple may also be incorporated in the holder block.

Beam Sources. Beam formation is at the heart of the MBE technique and the material from which the beam is to be formed determines the source design and also influences the choice of pumping system. In fact, MBE has become the generic term for a number of closely related techniques which are defined by the nature of the source material (Table 3).

Solid Sources. A typical design is illustrated in Figure 13. For low-vapor-pressure materials, such as Ga and Al, the operating temperature may reach 1200 °C. The crucible must therefore be refractory, of high purity, and chemically inert; the preferred material is pyrolytic boron nitride (PBN). The heater is a refractrory metal (usually W or Ta) wound noninductively and supported on PBN insulators; the cell is surrounded by Ta foil radiation shields. The flux is determined and regulated by the cell temperature, so measurement and control are crucial. Measurement is based on an optimally po-

Figure 13. A) A typical Knudsen source for group 13 elements; B) Section through the tapered crucible
a) Foil tube; b) Water cooling; c) Heater foil; d) Crucible; e) Thermocouple; f) Multilayer radiation shield; g) Thermocouple feedthroughs; h) Power feedthroughs; i) Radiation shielding; j) Spring-loaded W – Re thermocouple

sitioned thermocouple, usually W – Re (5 % and 26 % Re) and control is established by proportional integral derivative (PID) controllers and thermocouple feedback, with computer control of the deposition sequence so that temperature – time profiles for each cell can be programmed, together with shutter sequencing and substrate temperature.

The flux J at a distance d (cm) from the cell is given by:

$$J = \left(1.118 \times 10^{22}\right) \frac{pA}{d^2\,(MT)^{1/2}} \quad \text{atoms(molecules) cm}^{-2}\text{s}^{-1}$$

where p is the pressure in Torr (1 Torr $\simeq$ 133 Pa) of material of molecular mass M in the cell, A is the area of the orifice, and T the cell temperature in K. Typical fluxes at the substrate surface are $10^{14} - 10^{15}$ atoms (molecules) cm^{-2} s^{-1}.

Group 15 elements (group numbering according to IUPAC recommendations) evaporate as tetramers (P_4, As_4, Sb_4), and molecular beams from a conventional Knudsen source are consequently also tetrameric. There is evidence, however, that certain electrical properties of films of III – V compounds may be improved by the use of dimeric group 15 species and these can be produced with a special source known as a cracker cell. In essence this is two cells in tandem; a beam of tetramers is formed in the first by normal evaporation from the element and this beam is transmitted into a second cell, referred to as a "cracker," which is maintained at a higher temperature and fitted with baffles to maximize the number of collisions of tetramer molecules with heated surfaces. Under these conditions, the tetramers dissociate to form dimers and the resultant beam can contain up to

Table 3. Processes covered by the generic term MBE, the source materials involved, and some applications

Process	Source materials	Applications
Molecular beam epitaxy (MBE)	generic name, but now used for solid source systems, e.g., metals, Si, Ge, and elemental group 13 and 15 sources	magnetic films, silicon, III – V compounds, e.g., GaAs, (Al, Ga)As
Metal-organic molecular beam epitaxy (MOMBE)	group 13 organometallic compounds, e.g., triethyl gallium, trimethyl indium, (mostly volatile liquids); elemental group 15 sources	III – V compounds, especially GaAs and $(In_xGa_{1-x})As$
Chemical beam epitaxy (CBE)	group 13 organometallic compounds; group 15 hydrides (PH_3 and AsH_3)	III – V compounds and alloys, especially P-containing materials, e.g., $(In_xGa_{1-x})P$
Solid source molecular beam epitaxy (SSMBE)	usually applied only to Si and Ge elemental sources with electron beam evaporation	Si and SiGe alloys
Gas source molecular beam epitaxy (GSMBE)	applied mainly to Si and Ge growth from their gaseous hydrides (SiH_4, Si_2H_6, GeH_4)	Si and SiGe alloys
Atomic layer epitaxy (ALE); migration-enhanced epitaxy (MEE); growth interruption (GI)	a range of methods characterized by pulsed sources, usually elemental, and applied to III – V compounds and alloys	most III – V compounds and alloys

100 % of the dimerized species, depending on the temperature of the cracker region.

Although it employs a solid source, silicon deposition from elemental silicon is an exception, since it is referred to as Si MBE (or SSMBE), but is not strictly a molecular beam technique. It relies on the evaporation of Si from a Si boule, the central region of which is heated to ca. 2000 °C by a focused electron beam. This source temperature is necessary to obtain an adequate vapor pressure, but molten Si (*mp* ca. 1420 °C) is extremely corrosive and can only realistically be contained by solid Si. The arrangement is to mount the Si boule in a water-cooled copper hearth, which allows a solid outer region to be maintained, even though the central part is molten. The rest of the system is the same as for conventional MBE.

Gas and Volatile Liquid Sources. Although solid sources have provided the basis for MBE technology, volatile liquid and gaseous sources have important areas of application. In compound semiconductor technology, organometallic precursors such as trimethyl gallium (TMGa) or triisopropyl gallium (TiPGa) which in general are volatile liquids, are frequently used as the cation source while the gaseous group 15 hydrides (AsH_3, PH_3) can provide an anion source. They have the advantage of continuous replenishment from outside the UHV system, and operate at or just above room temperature, so potentially generate less contamination than a high-temperature solid source. This low-temperature concept is even more important for Si technology, where the very high-temperature electron beam evaporation process is being superseded by the use of gaseous hydrides (SiH_4, Si_2H_6). With both volatile liquids and gases, fluxes are normally controlled by mass flow meters, even though it is ultimately the pressure behind the cell orifice which determines the magnitude of the flux.

An additional feature in the growth of III – V compounds from group 15 hydrides is the necessity to dissociate (crack) them before they impinge on the substrate. The technology is similar to that used to produce dimer beams from group 15 elemental solid sources, but in this case the reason for predissociation is simply that the hydrides are too stable thermally to allow growth to occur directly.

The use of nonsolid sources has generated a terminology appropriate to each type and for reference to the literature it is important to define them, as indicated in Table 3.

Pulsed (Noncontinuous) Sources. Several modifications to the process of continuous deposition, particularly of III – V compounds and alloys, have been introduced, all based on interruption of growth. The modifications were introduced either to produce more perfect interfaces between layers of different composition or to grow material with superior electrical and optical properties at lower temperature. In the simplest version of growth interruption, the shutter of the group 13 element source, but not that of the group 15, is closed briefly (up to 120 s) to allow the surface to smoothen before deposition of the next layer is started.

Atomic layer epitaxy (ALE) and migration-enhanced epitaxy (MEE) involve periodic interruptions of both fluxes during growth; ALE

is based on an alternate supply of constituent elements to the substrate surface, regulated so that a complete monolayer is provided with each pulse. The adsorption of group 15 molecules is self-regulated by the group 13 atoms in the surface, but the latter can accumulate as the free element if the amount per pulse is too large. The MEE process also involves the alternating supply of cation and anion fluxes, and it is claimed that by reducing the surface concentration of the group 15 element during the impingement of the group 13 atoms, their surface migration rate is enhanced, resulting in smoother, higher quality growth at lower temperatures.

1.4.3. Monitoring Facilities

The vacuum environment of MBE growth allows a number of powerful diagnostic techniques to be used to monitor various stages of the process. The vacuum quality can be checked with a mass spectrometer to obtain quantitative information on the partial pressures of the background gases; characteristic patterns are observed which may indicate the presence of small leaks, or other contamination, e.g., an oxidized As_4 source. The total pressure in the system can be measured with a Bayert – Alpert ion gauge, and a second such gauge placed in the substrate position can be used to quantify the flux of atoms from the growth cells, manifest as a rise and fall in pressure when the shutter in front of each cell is opened and closed. The flux of dopant atoms is usually too small to be detected in this way, and calibration of these cells is performed indirectly, e.g., by measuring the electrical properties of doped layers.

A technique which can provide valuable information on the MBE growth process is reflection high-energy electron diffraction (RHEED). As shown in Figure 14 a beam of electrons of en-

Figure 14. A RHEED system used for monitoring MBE growth

Figure 15. Two-dimensional, monolayer-by-monolayer growth and the corresponding RHEED intensity modulation Θ is the coverage in monolayers.

ergy ca. 10 – 25 keV is incident at glancing angle (ca. 0.5 – 4°) on the substrate, and the diffracted beams strike a phosphor screen on the opposite side of the growth chamber. The diffraction patterns produced are related to the surface structure of the substrate (or deposited layer) and can be used to detect the structure of the surface during substrate cleaning, the presence of three-dimensional growth modes (rather than the desired monolayer-by-monolayer deposition), and the occurrence of modifications to the configuration of the surface atoms, the so-called surface reconstructions. In addition, monitoring the intensity of the specularly reflected beam allows a very accurate determination of the growth rate. This is possible because the deposition of each monolayer occurs by a "nucleation plus coalescence" process which results in an alternating roughening and smoothing of the surface (Fig. 15) which produces a corresponding intensity modulation of the specularly reflected beam at various stages in the growth. Since electrons are scattered out of the specular beam as the surface roughens, the intensity oscillates with a period equal to the time taken to deposit one monolayer of material; thus, not only can the number of individual monolayers deposited be counted, to give a very precise measure of thickness, but by timing the oscillations, an accurate measure of the growth rate is obtained.

1.5. Thin Films by Adsorption Processes

The outermost nanometer of a solid governs many interfacial poperties, including wettability, friction, and electrochemical reactivity. Very thin films of foreign materials on the surface may alter these properties. Consequently, a widely used method of controlling interfacial chemistry is to adsorb a monolayer of a surface-active agent (surfactant) onto the surface. Surfactants are organic molecules, normally adsorbed from solution, although vapor-phase adsorption is also possible.

Adsorbed monolayers are classed as physisorbed or chemisorbed, according to the nature of the interactions attaching the molecules to the surface. Although this division is useful, the distinction between chemisorption and physisorption is not sharp. Physisorbed films are stabilized only by van der Waals or dipolar interactions. Since the interaction with the surface is weak, the monolayers do not normally retain their integrity when the solid is removed from the adsorption solution. A practical example is the use of detergents to enhance the wettability of hydrophobic surfaces. In polymeric adsorbates, the relative weakness of the interaction with the surface is compensated by multiple interactions involving different parts of the polymer chain. The suppression of the growth of wax crystals

in diesel fuel is one important use of physisorbed polymers.

In chemisorbed films, a covalent or ionic interaction exists between the surfactant and the solid. This specific interaction with the solid increases the stability of the film and helps prevent multilayer formation, both of which lower the amount of additive required. Surfactants used in aqueous solution frequently also contain one or more long hydrocarbon chains. Hydrophobic interactions between the alkyl chains and water favor aggregation of the surfactant in solution and at a surface; van der Waals interactions between the hydrocarbon chains in the monolayer contribute additional stability to the adsorbed film.

In commercial applications, mixtures of surfactants are invariably used and the optimum adsorption conditions are developed empirically. The factors governing the choice of surfactant may be illustrated by the practical problem of controlling wettability. In the recovery of ore by flotation, surfactants are required that adsorb selectively to ore particles and make their surfaces hydrophobic. Aqueous solutions of sodium ethylxanthate ($C_2H_5OCS_2^-Na^+$) are commonly used for sulfide ores. It is believed that the monolayer is stabilized by a polar covalent bond between the mineral surface and the sulfur atoms of the surfactant. Metal oxides are more ionic than sulfides. In the flotation of oxide minerals, electrostatic interactions between the surface and an ionic surfactant are exploited. However, ionic interactions alone are insufficient for the formation of stable monolayers, and long hydrocarbon chains are also required. For example, dodecylammonium acetate is used in the flotation of negatively charged oxides, such as goethite and quartz. Conversely, anionic surfactants are used at low pH when the mineral surface is positively charged. Similarities in the chemical structure of the surfactant head group and the solid can be exploited, e.g., sodium stearate is used to make calcite hydrophobic. Typical surfactant concentrations are $10^{-5}-10^{-3}$ mol/L.

Surfactants can be deposited from dispersions as well as solutions. Double-chained cationic surfactants, such as $[CH_3(CH_2)_{17}]_2(CH_3)_2N^+Cl^-$, are widely used as fabric conditioners, even though they are virtually insoluble in water. These molecules are present in solution as lamellar mesophases and are adsorbed onto the surface as a result of electrostatic interactions.

Adsorption of monolayers from nonaqueous media requires surfactants that are soluble in organic solvents. A classical example is the adsorption of stearic acid from oil onto iron. The resulting densely packed monolayer acts as an efficient lubricant. Oil-soluble corrosion inhibitors, such as long-chain imidazolines, are highly efficient, even when present in monolayer quantities on the surface of steel.

The silanes are another important class of surface modifiers. Silanes, such as $NH_2(CH_2)_3Si(OCH_3)_3$ (APS), are used as coupling agents to promote adhesion of polymeric resins to mineral surfaces [36]. Hydrolysis of the methoxy groups yields free silanols which condense with hydroxyl groups on the surface to form strong covalent Si – O – Si bonds. The terminal functional group is free to couple to the resin: e.g., the amino group of APS can react with polyamide resins. Reactions between silanols strengthen the film by cross-linking, but also lead to polymerization, so the resulting thin films are rarely monomolecular – ten monolayers is a more typical thickness. Silane coupling agents can be applied, either from dilute aqueous solutions or as a minor component of a resin.

1.5.1. Self-Assembled Monolayers

Self-assembled monolayers (SAM) are densely packed monolayers formed by adsorption; the term is usually restricted to structurally well-defined monolayers that can be removed from the adsorption medium and characterized by a range of analytical techniques. The molecular architecture and physical properties of SAMs can be varied in a controlled way, in contrast to most of the systems used in commercial processes. Two types are most important: alkanethiols on metals and alkyltrichlorosilanes on oxides.

Long-chain alkanethiols of the generic structure $X(CH_2)_nSH$ adsorb on gold, silver, platinum, and copper (as well as on gallium arsenide and probably other materials) through the formation of a metal thiolate [37]. The chain length n is typically 10 – 21 and the tail group X can be any functional group chemically compatible with a thiol. The monolayers are stabilized by a strong metal – sulfur bond and by van der Waals inter-

actions between all-*trans* hydrocarbon chains. The tilt of the chains from the surface normal depends on the lattice parameters of the solid and varies from substrate to substrate: 30° on Au (111), 12° on Ag (111), and 57° on GaAs (100).

A SAM on gold can be prepared by immersing a freshly prepared gold mirror in a 10^{-3} mol/L solution of a thiol in degassed ethanol (Fig. 16). Adsorption is largely complete within the first few seconds, but a slow period of consolidation follows and many hours of adsorption may be needed before the limiting structure is reached. Multiple functional groups can be incorporated into SAMs by coadsorption of two or more thiols. The composition of a mixed monolayer does not in general reflect the composition of the adsorption solution and must be determined separately. In the study of interfacial processes such as wettability, surface reactivity, and electron transfer, SAMs of thiols on gold have been extensively exploited as model systems. Practical applications as electrochemical sensors and monolayer resists in microlithography are also being developed.

Figure 16. Formation of a self-assembled monolayer of an alkanethiol on gold

Alkyltrichlorosilanes ($X(CH_2)_nSiCl_3$) are similar to the silane coupling agents, but less prone to multilayer formation [38]. Elimination of HCl leads to the formation of siloxane bonds to oxide surfaces, in particular to silica. A substrate is typically immersed in a 0.1 % solution of the trichlorosilane in a 3:1 hexadecane/CCl_4 mixture at room temperature for 2 min, although the adsorption time depends critically on the amount of water present. SAMs of alkyltrichlorosilanes are densely packed and the hydrocarbon chains are oriented approximately perpendicular to the surface. One particularly versatile molecule is octadecyltrichlorosilane (OTS). An OTS monolayer on glass is 2.5 nm thick, chemically and thermally stable, highly hydrophobic, and resistant to chemical contamination.

1.5.2. Self-Assembled Multilayers

Multilayers can be built up in a controlled fashion by sequential adsorption of self-assembled monolayers. These multilayers are being developed principally for applications in nonlinear optics and optoelectronics, which require oriented thin films of molecules with large nonlinear susceptibilites. More than 25 layers have been built up by the following route at Eastman Kodak (Fig. 17).

An alternative approach, developed at the University of Texas and at AT & T Bell Laboratories, uses layers of alkyldiphosphonates ($^{-2}O_3P(CH_2)_nPO_3^{2-}$) held together by sheets of zirconium ions (Zr^{4+}) [39].

1.6. Langmuir – Blodgett and Related Techniques

Monomolecular films have been a subject of scientific interest for more then a hundred years, but it was not until 1917 that LANGMUIR introduced the film balance for the study of molecular films on water surfaces [40], the basis of today's experimental and theoretical concepts. He demonstrated that fatty acids of different chain lengths form insoluble monolayers at the air – water interface and that they occupy the same cross-sectional area. Therefore they are oriented perpendicular to the water surface. The transfer of the monomolecular film from the water surface onto a solid substrate provides a method of preparation which is now called the Langmuir – Blodgett (LB) technique, first published by BLODGETT in 1935 [41].

The LB technique is commonly used to produce highly ordered ultrathin layered films of monomeric or polymeric materials. The term "LB multilayers" is frequently used to describe the result of the assembly technique. The LB technique offers a number of advantages:

1) Film thickness can be controlled directly by the number of monolayers transferred.

Figure 17. Synthesis of organized multilayers of alkyltrichlorosilanes [38]

2) The orientation of the molecules in each layer can be precisely controlled.
3) The molecular species in each layer can be varied at will. This is of particular significance with regard to the bottom and the top layers of a multilayered assembly. The bottom layer is responsible for the interaction between film and substrate whereas the top layer determines the surface characteristics, e.g. wetting.
4) Control of the molecular interactions within the film allows optimization of properties such as conductivity or transparency.

Classical substances for the LB technique are amphiphilic molecules consisting of a long alkyl chain with a hydrophilic head group. Films are prepared by first depositing the amphiphilic material, dissolved in a volatile solvent immiscible with water, on the surface of water (subphase) contained in a trough. The subphase temperature is generally controlled by a thermostat. When the solvent has evaporated, the organic molecules may be compressed by a floating barrier to form a floating "two-dimensional" solid. Owing to their hydrophobic head groups, individual molecules align themselves during this process. Once the monolayer is compressed at a suitable constant surface pressure, the molecules can be transferred onto a hydrophilic substrate by dipping the substrate slowly into the subphase [42, 38]. Deionized water or dilute aqueous solutions of electrolytes have mainly served as subphase, although mercury, hydrocarbons, or glycerol have also been studied [43].

Depending on the substance and the substrate, transfer may occur during either the downstroke or the upstroke, or during both (Fig. 18). Three arrangements of amphiphiles in the multilayers (X-, Y- and Z-films) are possible (Fig. 19, see next page).

Figure 18. Spreading, compression, and deposition of amphiphilic molecules on the subphase

Figure 19. Structure of X-, Y-, Z-type amphiphilic multilayers

During compression, the monolayer undergoes a number of phase transformations. The different phases are in some respects two-dimensional analogs of gases, liquids, and solids, and can be identified by measuring the surface pressure of the monolayer as a function of the area per molecule. Figure 20 shows isotherms of an amphiphilic diacetylene monocarbonic acid at three different temperatures [44].

For the 5 °C isotherm, at an area of 0.33 nm^2 per molecule the first phase transition occurs to form the "liquid expanded" state. In this phase, the monolayer is coherent, except that the molecules occupy a larger area than in the "liquid condensed" state, which is formed at ca. 0.25 nm^2 per molecule. In the condensed phase, the molecules are closely packed and uniformly oriented. If further pressure is applied, the monolayer collapses and a sharp decrease in the pressure is observed. Frequently, amphiphilic substances show different condensed phases which differ by the mode of packing in two dimensions, depending on the applied surface pressure and temperature. Phase diagrams have been proposed which show the influence of temperature and chain length on the existence range of certain phases [45]. A specific state of packing of

Figure 20. Surface pressure – area isotherms of 12,8-diacetylene monocarboxylic acid, $C_{12}H_{25}-C{\equiv}C-C{\equiv}C-(CH_2)_8-COOH$, at the air – water interface on 10^{-3} mol/L $CdCl_2$ subphase, pH 6.1 at three temperatures

the molecules on the substrate can be obtained by choosing suitable transfer conditions (temperature, surface pressure, etc.).

Molecular Design. Several factors affect the suitability of a substance for the formation of a monolayer:

Solubility
Volatility
Interaction between molecules
Interaction with the subphase
Chemical stability under spreading and transfer conditions

The deposition of the floating monolayer can be hindered if the affinity of the film to the substrate is too weak. The formation of multilayers is impossible if the substance lacks affinity to itself. Molecules which are able to form monolayers at the air – water interface can be divided into three classes:

1) Low molecular mass substances
2) Amphiphilic polymers
3) Polymers with a rod-like backbone and flexible side chains (hairy rods)

1.6.1. Low Molecular Mass Substances

Most of these substances with high affinity to the water subphase consist of a hydrophilic head group and at least one long alkyl chain. The classical film-forming substances are fatty acids [46], their derivates and salts, but a number of other substances have been found to form LB layers (Table 4).

Hydrophilic head groups can be formed by nearly all kinds of polar functional groups. The amphiphiles often behave like the corresponding fatty acids.

Aromatic compounds, some of which contain heteroatoms, as well as anthracene derivatives, have been modified by polar groups to form amphiphile head groups. Liquid crystalline (mesogenic) compounds inherently form layered structures; their incorporation increases the thermal and mechanical stability of a two-dimensional fluid phase. Properties of LB films such as selective binding to particular surfaces or conductivity (Section 2.6.1) can be achieved by attaching long alkyl chains to the suitable functional moieties; LB layers containing dyes and ionophores have been prepared. On the other hand, ferrocene is an example of a compound which forms LB layers, if polar substituents are attached.

Lipids are the matrix-forming ingredients of biological membranes and are therefore an important class of LB layer materials. These molecules often show complicated behavior at the air – water interface, due to the presence of two hydrophobic tails.

Porphyrins and phthalocyanins are examples of more complex LB layer molecules. They can carry a variety of functional groups, some of which deviate from the normal requirement of having well-defined head and tail groups. This deviation is reflected in their monolayer properties; the molecules form multilayer stacks in which the structure and stability of the film is governed by molecular packing rather then by hydrophilic – hydrophobic interactions.

For some amphiphiles it may be necessary to add certain ions to the subphase in order to ensure good deposition behavior by salt formation. For example, bivalent ions, e.g., Cd^{2+}, in the subphase are sometimes needed to achieve transfer of fatty acids from the water surface onto solid substrates. They are then deposited as Cd salts.

Monolayers can also be built up by a mixture of different molecules; LB films containing molecules which do not themselves form stable films can be prepared from a mixture with a suitable partner.

1.6.2. Polymeric Amphiphilic LB Layers

Thermal and structural stability is limited by the melting temperature of the compounds. Thermal desorption occurs readily above the melting temperature. The stability can be enhanced by using polymers. Such polymers can be obtained from amphiphilic monomers by in situ polymerization of monolayers or by spreading preformed amphiphilic polymers. The functional groups active toward polymerization of amphiphilic monomers are typically diacetylenes [47], acrylates, methacrylates, or cinnamic acid derivatives (Table 5).

Polymerization can be performed on the water surface or in the deposited film. It is gener-

ally initiated by irradiation or by the addition of radical-forming substances which can be excited directly or via energy transfer from sensitizers.

The topochemical polymerization of diacetylenes proceeds within LB layers with retention of the crystalline order and the layer structure. The active group to be polymerized can be located on either end of the monomer: near the hydrophilic end or in the hydrophobic part. Oxiranes undergo very little structural change during their ring-opening polymerization.

In polycondensation, the constituent molecules join together with the elimination of another molecule. One of the few examples in the present context is the reaction of a monolayer of octadecanal $C_{17}H_{35}CHO$ with a preformed polymer (poly-L-lysine) which is initially dissolved in the subphase.

Preformed amphiphilic polymers have alternating hydrophilic and hydrophobic segments in different parts of the polymer. Spacer groups can be used to decouple the motions of the main

chain from that of the amphiphilic side groups. Polymer analogous reactions, if carried out in the deposited multilayer system, may be used to prepare thin films of insoluble polymers, e.g., poly(imides) and poly(*p*-phenylenevinylenes), on solid substrates.

1.6.3. Hairy Rod Polymers

Rod-like polymers can not be classified according to the rules developed for the behavior of amphiphilic compounds at the air – water interface. They exhibit cylindrical symmetry, with low-polarity segments distributed equally over the whole molecule (Fig. 21, see previous page). These polymers lie flat on the surface. It is essential to surround the rod-like polymers with conformationally mobile side chains. This provides fluidity of the monolayer at the air – water interface and screens direct backbone interactions. The alkyl chains act as chemically attached solvent molecules. Transferring monolayers of hairy rods onto solid substrates aligns the stiff polymer backbones parallel to the dipping direction, producing highly ordered multilayers (Fig. 22) [48].

Typical examples of such polymers are phthalocyaninato-(poly)siloxanes (PcPS), several polyglutamates in the α-helical conformation, cellulose alkylethers, specifically substituted polysilanes, and poly(*p*-phenylenes).

Film Deposition. Figure 23 is a schematic diagram of a typical LB trough. The bath (a) is usually made of PTFE or PTFE-coated material. A moving barrier (b) allows control of the pressure applied to the monolayer. The pressure-control device receives information from a pressure sensor (e) on the water surface. A motor (d) is used to lower and raise the solid substrate (e). The trough is temperature controlled.

Two methods can be employed to measure surface pressure. In the Wilhelmy technique, the surface tension is measured by weighing a hydrophilic plate which is dipped through the monolayer into the aqueous subphase. In the Langmuir method, the difference in surface pressure is measured between the pure air – water surface and the surface covered with the film.

The transfer of monolayers requires a constant surface pressure. Thus, during transfer, the barrier moves continuously toward the substrate.

Other Types of LB Trough. The circular trough (Fig. 24) [49] has a simple reliable motor drive for the barriers (linear troughs require special provision to convert the circular motion of the motor to a linear one). The multicompartment circular trough has two independent drive barriers enclosing the monomolecular film, so that molecules can be compressed as well as being transported from one compartment to another. This allows, for example, a change of subphase while the trough is in use. The texture of the films transferred from the trough reflect the state of order of the monolayer at the air – water interface. The texture is strongly influenced by the flow conditions of the monolayer in compression and transfer. Since the flow processes depend on the trough design, different textures may be obtained by using different designs.

In the constant-perimeter barrier trough [50] some of the difficulties encountered with conventional compression systems can be avoided

by enclosing the monolayer within a continuous, flexible plastic barrier. Usually, a PTFE band is stretched around four vertical glass spools and a rod. The rod can be rotated to take up the slack as the area is changed.

Double linear troughs [42] facilitate deposition of alternating layers. The substrate can be handed over automatically from one trough to another above or below the water level, which allows preparation of a variety of periodically or aperiodically stacked multilayer systems.

All troughs described so far are specifically designed for small-scale production of LB films (typical areas $1-20\,cm^2$). The number of lay-

ers on a substrate is limited by the subphase area and substrate size. For deposition of larger numbers of layers, continuous troughs have been constructed. In principle, the Langmuir time sequence (spreading, compressing, deposition) is replaced by a sequence distributed in space; all the elementary operations take place simultaneously in different compartments. Several different troughs have been developed.

In a trough with a steadily flowing subphase (Fig. 25) [51], the horizontal trough is replaced by a flow channel. Water as subphase is circulated to generate a steady laminar flow film on the ramp and thereby compresses the molecules on the surface to form a monolayer. The amphiphile can be continuously spread and deposited.

Figure 25. Monolayer compression of rod-type molecules in a continuously working LB trough with a steadily flowing subphase

A roller trough (Fig. 26) [52] is divided into four compartments connected by rollers which transport amphiphilic molecules according to the direction of rotation. In the first compartment, the amphiphile is continuously spread by a microelectrovalve and slowly transported into the second compartment where a constant surface pressure of a few mN/m is maintained. The speed of the second roller transporting the molecules into the third compartment, where deposition takes place, is adjusted according to the amount of film removed by a dipping substrate. If the surface pressure exceeds the desired value, an auxiliary roller is actuated to take the excess film to a fourth compartment, where it is removed via a capillary tube.

Another possibility of building LB multilayer structures is the horizontal lifting method (Schäfer's method) [53], introduced by Langmuir and Schäfer in 1938. Schäfer's method is useful for deposition of very rigid films, such as those located in the two-dimensional solid region of the surface – pressure – area diagram (see Fig. 20). A flat substrate is placed horizontally on the compressed monolayer. When this substrate is lifted and separated from the water surface, the monolayer is transferred onto the substrate. In theory, the molecules should maintain the same orientation; in practice, this is not always the case. The molecules near the outer rim of the substrate tend to lose their orientation.

Figure 26. A) Continuously working LB trough with rollers
a) Reservoir; b) Microelectrovalve; c) Rollers; d) Pressure sensor; e) Substrate; f) Capillary tube
B) Transport of amphiphilic molecules

A large number of experimental conditions have to be taken into account for the deposition of LB layers: control of atmosphere, temperature, and humidity around the trough is recommended. The LB trough is usually installed in a laminar flow box to ensure a dust-free environment. The trough should stand absolutely shock free. Since the spread substance has an extremely large surface, special care has to be taken to avoid chemical reactions with the atmosphere or photodegradation.

The water is usually deionized through a Millipore system that contains a final filter to remove bacteria. It is particularly important to keep the subphase free of all surface-active substances. Ionic content and pH must be carefully controlled.

A variety of solids can be used as substrates: glass, quartz, or silicon wafers are commonly used, but in principle most metals or semicon-

ductors can serve as substrates, depending on the desired application of the film. Hydrophobization may be necessary. Cleaning is essential; even trace impurities may adversely affect the deposition process.

1.7. Electrochemical Deposition Processes [54–79]

1.7.1. Scope

Electrodeposition is the process of producing a thin layer on a substrate, under controlled conditions, via an electrochemical reaction. The choise of substrate and coating may encompass a large number of single metals and alloys. The substrate may be polymeric, ceramic, or a composite. The coating may be a single metal, an alloy, a polymer, a ceramic, or a metal – polymer or metal – ceramic composite. In practice, the choice is severely restricted by technical and economic constraints and there is a trend toward relatively cheap substrates (ferrous, zinc, aluminum, or copper-based alloys) as bulk constructional materials. The most common case of electrodeposition is the d.c. electroplating of a metallic coating onto a metal substrate, the workpiece being made the cathode of the electrolytic cell. However, the field of electrodeposition is much wider, including the production of anodic films (e.g., metal oxides or polymers) and electrophoretic or electropolymerized deposits.

The objective of an electrodeposition process is to produce a deposit which adheres well to the substrate and which has the required mechanical, chemical, and physical properties. It is essential that the process is predictable and reproducible. On the other hand, many metals may (by modification of the bath and plating conditions) be deposited with different properties. For this reason it is not possible to define a single set of conditions for electroplating each metal. Electrolyte composition, current density, temperature, etc. depend on the deposit properties required. Electrochemical techniques are widely used in surface finishing to produce thin layers (typically 1 – 100 µm) with particular engineering, chemical, corrosion resistance, decorative, or electronics properties.

1.7.2. Electrochemical Deposition of Metals and Alloys

The deposition of metal onto a substrate can occur by three electrochemical routes: electrodeposition, electroless plating, and immersion plating. These all involve reduction of a dissolved metal ion, M^{z+}, via electron gain to form the metal M:

$$M^{z+} + ze^- \longrightarrow M$$

The three deposition processes are differentiated by the source of the reducing electrons.

The most commonly used technique is electrodeposition or electroplating. An externally applied current provides the electrons. An electroplating bath consists of an anode and a cathode in an electrolyte, usually an aqueous solution of a salt of the metal to be plated. The item to be plated is made the cathode and reduction of ions to metal occurs here. Anodes are made either of an inert conductor, e.g., platinum or graphite, or of the metal which is being plated. Oxidation occurs at the anode. Inert anodes evolve oxygen as current flows. Anodes of the plated metal are dissolved. The thickness is mainly determined by the deposition time. Electrodeposits can be up to 100 µm thick, but thinner layers are much more common.

Electroless plating does not utilize an external power supply; instead, metal ions are reduced by chemical agents in solution and deposition is controlled so that plating occurs only on the substrate. This is achieved by an activation pretreatment of the workpiece which acts to catalyze the reduction or as a nucleation site for film growth. Metal is deposited on both conducting and nonconducting surfaces. The rate of electroless plating is considerably slower than electroplating. It is only used to deposit thin layers, typically 0.25 – 1 µm.

Immersion plating involves plating of a base metal substrate by reaction of that metal with the salts of a more noble metal, via reduction and deposition of the dissolved ions, and oxidation of the surface of the substrate. This technique has limited application, owing to restrictions on the types of metal that can be plated, and the limited thickness of deposits.

Electroplating. Alloys and composites can also be deposited by electrolysis. The uses of electroplated coatings include engineering, electronic, and decorative applications. The properties and applications of commonly electrodeposited metallic coatings are summarized in Table 6. The essential components of the electroplating process are shown in Figure 27.

Table 6. Properties and applications of electrodeposited metals

Property	Metals and alloys used	Example of use
Corrosion resistance	Cr, Ni, Sn, Au, Zn, Rh, Cd	corrosion protection, food cans
Buildup of material on surface	Cr, Fe, Ni	reclamation of worn parts
Decorative appeal	Cr, Au, Ag, Pt, Ni, 70:30 Cu – Zn	jewelry, cutlery, general decoration
Wear resistance	Cr, Ni, Fe, Sn, Ru, Pd	rollers, pistons, bearings, contacts, switches
Hardness	Cr, Ru, Os	molds, presses
Reflectivity (optical or thermal)	Cr, Rh, Au	lamps, projectors, aerospace screens and visors
Electrical conductivity	Cu, Ag, Au	printed circuit boards, antennae, bus bars, cables
Oil retention	Cu, 65:35 Sn – Ni	hydraulic systems, lubrication
Solderability	Ni, Sn, Cd, 60:40 Sn – Pb	printed circuit boards, electrical contacts
Low contact resistance	Ag, Au, Rh, Pd, Sn, 80:20 Pd – Ni	electrical contacts

Figure 27. Principle of electroplating
a) Anode; b) Power supply, d.c.; c) Electroplated metal layer; d) Cathode (workpiece); e) Electroplating tank
The electrolyte in the plating bath consists of: water, source of metal ions, conducting salts, buffer, and additives.

The source of metal ions for the cathode reduction reaction may be a complex cation or an anion, rather than the simple metal cation. Examples include $Zn(CN)_4^{2-}$ and $Sn(OH)_4^{2-}$ in cyanide – zinc and alkaline – tin plating baths. The mass of metal deposited is directly related to the charge transferred:

$$w = \frac{\varphi M Q}{zF}$$

where w is the mass of electroplated metal, M the molar mass of metal, Q the electrical charge, φ the cathode current efficiency for metal deposition (< 1), z the cation charge, and F is the Faraday constant, 96 485 C/mol.

Most electroplating processes are carried out at constant current. If uniform deposition is assumed, the average rate of deposition per unit area is:

$$\frac{w}{tA} = \frac{\varphi M I}{zF}$$

where A is the electrode area, t the time for deposition, and I the current. The rate of thickness development can be expressed as:

$$\frac{x}{t} = \frac{\varphi M I}{\varrho z F A} = \frac{\varphi M i}{\varrho z F}$$

where x is the deposit thickness, A the electrode area, and ϱ the density of the deposited metal. The current efficiency depends on the process used. Electroplating baths are usually designed to have a high efficiency, $0.9 < \varphi < 1$, but some baths, e.g., chromic acid – chromium, are operated at much lower cathode efficiencies, typically $0.1 < \varphi < 0.2$. The most common secondary reaction at the cathode is the evolution of hydrogen which creates safety/environmental problems and the possibility of hydrogen damage to the plated deposit via embrittlement or blinding of the surface.

The throwing power of a bath is a measure of how evenly the workpiece is plated. It is assessed by comparing the plating thickness of areas at different distances from the anode. A high throwing power leads to even coverage all over the workpiece. This is important when coating items with recesses or other surface features. The main factors which affect throwing power are bath composition, temperature, and current density. A conductive electrolyte aids current flow to all parts of the cathode, minimizing the effects of increased resistance with increased distance.

If there is a high concentration of metal ions in the bath, mass transport considerations should not affect the throwing power. An even current density leads to even plating across the workpiece, so the metal plating is affected by the conductivity of the substrate surface. How evenly a metal is plated can be enhanced by auxiliary anodes (usually inert), to help distribute current to inaccessible areas.

Where possible the anode is made of the same metal as that being plated. This dissolves as plating occurs. To maintain a constant metal ion concentration, the rate of dissolution at the anode must be the same as the rate of deposition at the cathode. The current efficiency of the two electrodes must therefore be similar. It is important to minimize production of insoluble sludge as the anode dissolves (from impurities in the metal or particles left over from fabrication). Incorporation of impurities in the plate can affect the smoothness, conductivity, and contact resistance of the metal. The structure of the anode can also be important. A coarse-grain anode can dissolve unevenly, leading to fluctuations in metal ion concentration. The best anodes have a nonporous rolled structure and dissolve steadily at steady current.

Before electroplating, the surface must be cleaned to remove dirt, grease, and surface oxide. This is essential to give good adhesion between the metal plate and the substrate.

Mechanical cleaning methods include abrasion, shot blasting, and polishing. These remove scale and some dirt, but further treatment is usually necessary.

Solvent cleaning is used to remove residual oils and greases from the workpiece. This allows the surface to be better wetted by water-based electrolytes, but will not remove oxide layers.

Alkaline cleaners remove grease, soils, and scale from the metal surface. They consist of a mixture of alkali salts to saponify oil and grease to a water-soluble form, detergents to aid wetting by lowering surface tension at the metal – soil – solution interfaces, sequestering agents such as sodium gluconate to prevent precipitation of metal ions as insoluble hydroxides or carbonates, and a water softener to prevent hard water forming scale or scum on the surface. Alkaline cleaning is often carried out electrolytically. Cleaning is enhanced because the evolution of gas bubbles at the metal – solution interface dislodges soiling and transports fresh cleaner to the site.

Acid pickling is used to remove impurities by chemical attack and to stabilize impurities by ionic dissolution. An acid pickle removes oxides and scale from the surface of a metal and is often used after alkaline cleaning. A number of acids are used, either individually or as a mixture. These include nitric, sulfuric, hydrochloric, hydrofluoric, and phosphoric acids at concentration 2 – 85 %, depending on the metal and finish needed. Acid pickles are usually heated to 50 – 80 °C. As in the case of alkaline cleaners, electrolytic cleaning is often used to improve pickling.

When the plating process starts, the metal is deposited onto a surface that has a different structure from the plate. This is due to it being a different type of metal, to surface impurities, or to the surface having been machined. This can lead to poor adhesion between the base and the plated layer. Surface preparation such as the techniques outlined above improves adhesion by removing impurities and oxides, but there may still be some difference in structure between the substrate and the plate. Adhesion between these layers is often enhanced by deposition of a thin "strike" plate of metal before the main deposit is applied.

A strike plate is electrodeposited from a low-concentration solution. Such solutions have relatively low throwing power and efficiency. At low current density, a slow plating rate leads to good adhesion of the metal onto the substrate. The strike solution is used to build a good basis upon which to plate from the high-concentration main tank.

Plating baths are a mixture of metal salts, electrolytes, and trace additives which modify the plating characteristics. The precise makeup of commercial baths and chemicals is usually secret, but general functions of each component are well documented.

The metal ion to be plated is kept at high concentration, usually 1 – 3 mol/L. It may be either the simple hydrated ion or a complex. If the deposition becomes mass transport controlled,

owing to a lack of metal ion at the cathode surface, plating quality is impaired because plating is now favored at sites on the workpiece that are easily accessible to the solution, and the lack of metal ions available for reduction promotes electrochemical side reactions. For this reason the concentration of metal ion is kept high.

Items of relatively simple shape are usually coated with solutions of the simple hydrated ion, derived from a salt. This is because the higher throwing power of complex ions is not needed. There are exceptions to this, e.g., when the metal being deposited is difficult to dissolve. To electroplate complicated shapes higher throwing power is needed, utilizing a complexed metal ion electrolyte or auxiliary anodes.

To maximize the conductivity of the bath, high concentrations of electrolyte are added; acidic, alkaline, and neutral electrolytes are used, e.g., H_2SO_4, KCN, NaOH, NaF, KF, NaCl, and NH_4Cl.

Complexing agents are added to make the deposition potential more negative, if it is necessary to prevent spontaneous reaction between the plating ion and the cathode material. For example, plating copper onto iron, the copper ions in solution attack the metal surface, dissolving iron:

$$Cu^{2+} + Fe \longrightarrow Cu + Fe^{2+}$$

This chemical reaction will lead to a very poor deposit, both porous and badly adherent.

Complexing agents can modify the redox potential of the Cu^{2+}/Cu couple so that it is more negative than the Fe^{2+}/Fe couple and the above reaction is no longer favorable thermodynamically. Common complexants are cyanide (CN^-), pyrophosphate ($P_2O_7^{4-}$), and hydroxide (OH^-). Complexing agents can also prevent passivation of dissolving anodes which maintains current efficiency.

The structure, morphology, and properties of the electroplate can be modified by low concentrations of organic molecules. The exact identity and concentration of additives for specific baths is kept secret by commercial suppliers. There are four general types of additive.

Brighteners produce a visually brighter or more shiny surface finish, by reducing the microscopic roughness of the deposit. The electrical properties are unaffected and brighteners are used when decorative appearance is important. Relatively high concentrations (g/dm^3) are used.

Levelers act by adsorption at points on the plating surface where there would be rapid deposition of metal. The adsorbed molecules reduce the rate of electron transfer, slowing the plating rate at these points and making plating across the whole workpiece more even. Many additives act as both brighteners and levelers.

Structure modifiers act by changing the electrodeposit structure to optimize particular properties of the plate. They are used when the plating is required to have certain mechanical properties, e.g., wear resistance for electrical contacts.

Wetting agents facilitate the release of gas from the cathode surface. Inclusion of hydrogen can cause the deposit to become brittle and prone to cracking.

Some tyical electroplating conditions are summarized in Table 7.

Metals are usually electroplated to a thickness of 1 – 100 µm. Deposits below 1 µm are generally too porous, and a plating thickness greater than 100 µm is usually ruled out by considerations of cost and time, although chromium plating may give thickness up to 500 µm, in special cases. Plating thickness for a particular metal is determined by the current, time, area, and electrode efficiency. For any electroplate, the thickness can be controlled by adjusting the current and time of plating. Most plating baths are current controlled and thus operated at known current densities.

The quality of the plating is affected by the rate of growth of the metal. If the plate is build up slowly, the microstructure is well defined, with layered, ridged, or block formation. If the plating rate is increased, a less dense, polycrystalline solid results. At high plating rates, nodules and dendrites of metal form. At the maximum deposition rate the metal goes down as a powder which does not bond to the surface. The change in plating characteristics with rate is mainly due to mass transport considerations. When the metal is deposited slowly, there is time for metal ions to diffuse to the cathode surface and there is always a high concentration of metal

Table 7. Typical process conditions for electroplating single metals [58]

Metal	Electrolyte composition, g/dm^3	Temperature, °C	Current, mA/cm^2	Current efficiency, %	Additives	Anode	Characteristics
Cu	$CuSO_4$ (200–250) H_2SO_4 (25–50)	20–40	20–50	95–99	dextrin, gelatin, S-containing brighteners, sulfonic acids	P-containing rolled Cu	not suitable for iron and iron alloy substrates; high current, but low throwing power; additives essential
	CuCN (40–50) KCN (20–30) K_2CO_3 (10)	40–70	10–40	60–90	Na_2SO_3	O_2-free, high-conductivity Cu	good throwing power; deposits adhere well and are bright; used as undercoat; cyanide decomposes at anode
Ni	$NiSO_4$ (250)	40–70	20–50	95	coumarin, saccharin, benzenesulfonamide acetylene derivatives	Ni pellets or pieces	H_2 evolved with deposition; additives depend on purpose of deposit; medium throwing power
	$NiCl_2$ (45) H_3BO_3 (30) pH 4–5						
	Ni sulfamate (600)	50–60	50–400	98	not essential; naphthalene-1,3,6-trisulfonic acid	Ni pellets or pieces	good throwing power; some H_2 with additives, mirror finish at 400 mA/cm^2
	$NiCl_2$ (5) H_3BO_3 (40) pH 4						
Ag	$KAg(CN)_2$ (40–60)	20–30	3–10	99	S-containing brighteners	Ag	good throwing power; functional or decorative
	KCN (80–100) K_2CO_3 (10)						
Sn	$SnSO_4$ (40–60)	20–30	10–30	90–95	phenol, cresol	Sn	poor throwing power; additives essential
	Na_2SnO_3 (50–100) NaOH (8–18)	60–80	10–20	70		Sn (control current)	good throwing power, but uses twice charge (Sn^{4+})
	$SnCl_2$ (75)	65	50–200	90	SCN-disulfononaphthalinic acid	Sn	reasonable throwing power; more stable than $SnSO_4$; rarely used
	NaF (37) KF (50) NaCl (45) pH 2.5						
Zn	NH_4ZnCl_3 (200–300) NH_4Cl (60–120) pH 5	25	10–40	98	dextrin, organic additives	Zn	poor throwing power; additives essential

ions available for reduction. Since deposition is slow, the metal atoms can form organized, well-ordered structures. When the rate is increased, the concentration of metal ions at the cathode is lower. Despite the short-range order in the structure the faster growth rate does not allow long-range lattices to form (polycrystalline). At high deposition rates, the metal ions arrive quickly at the cathode, and do not form ordered structures. The metal ion concentration at the surface becomes much lower than that of the bulk electrolyte, promoting the growth of nodules and dendrites since plating is favored further from the plane of the workpiece surface where there is a higher concentration of metal ions. The formation of dendrites is further favored since they cause an increase in surface area which reduces the overall current density.

The limiting factor in deposition rate is diffusion-controlled mass transport of the metal ion. At a particular temperature and electrolyte concentration, this has a maximum value (maximum rate of deposition). Deposits laid down this fast have very little structure and form powders which are easily removed by physical agitation. For a typical bath, the limiting current density is ca. 70 mA/cm^2. To ensure good adhesion, the current is kept at a much lower level. The main way of increasing plating thickness is to lengthen the plating time.

Electroless Deposition. In electroless deposition, the substrate acts as a catalyst for a spontaneous redox reaction. No external current is required and the process takes place by immersion of the workpiece in the plating bath. It is essential, however, that the substrate is pretreated so that deposition of metal takes place over the entire surface. Under constant process conditions, deposition takes place at a constant rate and the deposits tend to be microcrystalline, with the alloying element (e.g., P or B in nickel deposits) in solid solution. Despite the relatively high cost of electroless plating (compared with electrolytic deposition), the technique offers the advantages of a very uniform deposit thickness, even on workpieces with complex shapes. In Ni – P deposits, heat treatment (say 400 °C for 1 h) after deposition can increase the hardness (typically from 500 to ca. 1000 VHN) owing to crystallization of an Ni_3P dispersion throughout the coating. In addition to a metal salt and a suitable reducing agent, electroless plating solutions are formulated with additives such as complexants, stabilizers, pH buffers, accelerators, and brighteners to provide stable electrolyte solutions and the required deposit characteristics.

The most common electroless deposits are copper (to produce conductive tracking on printed circuit boards) and nickel (as a corrosion-resistant and engineering coating). Copper deposition is commonly carried out from an alkaline bath containing formaldehyde as the reducing agent while nickel baths commonly contain hypophosphite (Ni – P deposits) or less commonly borohydride (Ni – B). Typically, Ni – P deposits contain 3 – 15 wt % Ni.

Oxidation of the reducing agent must have an electrode potential which is more negative than that of the metal deposition process (Table 8). In electroless copper deposition from a bath containing formaldehyde, the simplified reactions are deposition of copper by reduction of its ions at cathodic sites:

$$Cu^{2+} + 2e^- \longrightarrow Cu$$

Table 8. Standard electrode potentials of reactions in electroless and immersion deposition

Reversible electrode process	Electrode potential∗, V
$Ag^+ + e^- = Ag$	+0.799
$Cu^{2+} + 2e^- = Cu$	+0.337
$HCOOH + 2H^+ + 2e^- = HCHO + H_2O$	+0.056∗∗
$Ni^{2+} + 2e^- = Ni$	−0.250
$Fe^{2+} + 2e^- = Fe$	−0.440
$H_2PO_3^- + 2H^+ + 2e^- = H_2PO_2^- + H_2O$	−0.500
$Zn^{2+} + 2e^- = Zn$	−0.763
$HCOOH + 2H^+ + 2e^- = HCHO + H_2O$	−1.07∗∗∗

∗ Relative to standard hydrogen electrode at 25 °C. ∗∗ At pH 0. ∗∗∗ At pH 14.

accompanied by reduction of formaldehyde to formic acid at anodic sites:

$$HCHO + H_2O \longrightarrow 2H^+ + 2e^- + HCOOH$$

The overall redox process on the metal surface is:

$$Cu^{2+} + HCHO + H_2O \longrightarrow Cu + 2H^+ + HCOOH$$

In electroless deposition from baths containing hypophosphite, the simplified reactions are as follows. The anodic reaction is oxidation of hypophosphite to orthophosphite:

$$H_2PO_2^- + H_2O \longrightarrow H_2PO_3^- + 2\,H^+ + 2e^-$$

and the cathodic reaction is deposition of nickel:

$$Ni^{2+} + 2\,e^- \longrightarrow Ni$$

The overall redox process on the metal surface is:

$$H_2PO_2^- + H_2O + Ni^{2+} \longrightarrow H_2PO_3^- + 2\,H^+ + Ni$$

It is important to note that:

1) The substrate metal and the deposited metal must support the electrode process in a catalytic manner
2) In the case of noncatalytic surfaces, the electroless process may be initiated by preliminary deposition of a catalytic metal (as in the case of plastics) or brief electrolytic deposition of the coating metal by passing a current for a short period
3) The process must be operated so as to avoid spontaneous decomposition of the electrolyte in the bath or on the tank surfaces
4) A pH decrease accompanies the overall process
5) The reducing agent is depleted and its oxidation product accumulates
6) The source of metal, i.e., Ni^{2+}, declines in concentration as the bath is used
7) In practice, the deposit is an alloy with a significant phosphorous level ($< 15\,\%$), showing that the above reactions are greatly oversimplified.

Points (4), (5) and (6) are addressed by planned makeup additions to the electrolyte.

By suitable formulation of the bath, electroless deposition can produce single metals, or metals containing a nonmetal component (e.g., P or B). In addition, special baths are available for the deposition of composite "inclusion" coatings, e.g., Ni – PTFE (as a nonstick coating) or Ni – SiC (as a wear-resistant coating), the inert particles being introduced to the electrolyte by agitation and/or surfactant dispersion techniques.

Immersion Deposition. If steel is dipped in a solution of copper sulfate, a deposit of copper is spontaneously formed on the surface of the steel. This reaction can be explained with reference to the electrochemical series (Table 8). The more positive (noble) redox system is reduced (deposition) while the more electronegative (base) is oxidized (dissolution).

The surface of the steel consists of a mixed electrode comprised of a mosaic of anodic and cathodic sites; the following reactions take place as the standard electrode potential for copper is more positive than that of iron. Anodic site:

$$Fe \longrightarrow Fe^{2+} + 2\,e^- \;+0.44\,V$$

Cathodic site:

$$Cu^{2+} + 2\,e^- \longrightarrow Cu \;+0.34\,V$$

Overall mixed-electrode reaction:

$$Fe + Cu^{2+} \longrightarrow Fe^{2+} + Cu \;+0.78\,V$$

The deposition of copper continues until almost the entire surface of the steel is coated. At this point there are insufficient anode sites left to dissolve (oxidize) and supply electrons for the cathodic reaction, and deposition ceases. Copper is usually deposited to a thickness of ca. 1 µm. Deposits tend to be very porous and adhere poorly to the substrate. The copper solution becomes contaminated in a relatively short time with ions of the base metal. These considerations limit the applications of immersion plating. It is normally used to produce deposits of silver, gold, or palladium on base metals. Examples include the deposition of gold onto nickel-clad printed circuit boards and the metallization of printed circuit plastics with palladium by deposition onto a tin layer.

1.7.3. Electrophoretic Coatings

Electrophoresis is the migration of charged organic molecules to electrodes of the opposite charge. At the electrode, the particles accumulate and deposition follows rapidly. In the organic coating of automobile bodies, prior to the finishing coats of paint, electrophoretic coating is also known as electropriming, electropainting, or electrocoating. It is used to deposit films 1 – 20 µm thick, the majority of applications being in the range 4 – 10 µm. These films have high corrosion resistance and an even coverage over the whole workpiece.

There are two types of electropriming: anodic and cathodic. Both use a water-based primer solution as the electrolyte. Water is favored as the solvent because it is cheap, harmless, and effluent treatment is straightforward.

In anodic coating, the article to be coated is given a positive charge. A water-insoluble, organic acid resin is dispersed in water by the action of a base to form colloidal-size anions:

The anions are attracted to the anodic workpiece where water is electrolyzed to H^+ and O_2 by removal of electrons:

$$2\,H_2O \longrightarrow 4\,H^+ + O_2 + 4\,e^-$$

The protons produced neutralize the resin, which is deposited as an insoluble, resistive film of (**1**).

The chemistry of the more commonly used cathodic electrocoating is similar in many ways. Acid is used to form colloidal cations from insoluble aminated resins:

As these ions collect at the cathode, electrolysis of water produces hydroxyl ions and hydrogen:

$$4\,H_2O + 4\,e^- \longrightarrow 2\,H_2 + 4\,OH^-$$

The resin reacts with the hydroxyl ions to deposit on the surface as an insoluble, resistive layer of (**2**).

Additives can be mixed with the resins to modify their properties. Examples are metals, metal oxides, carbon, sulfur, and cellulose. These are added as colloidal-sized particles which gain a positive charge by adsorption of hydroxonium ions in the case of cathodic electropainting. Large particles can migrate under the influence of a few charged ions. Electropriming is usually performed onto a metal substrate. The quality of the coverage is affected by the preparation of the metal surface. Conventional cleaning and degreasing techniques are often used, but the adhesion of some primers is enhanced if the base metal has been phosphated prior to electrocoating.

The high throwing power of electropainting is due to the resistive character of the paints. Once a layer has formed, this electrically insulates the surface, preventing further deposition. Coverage on less heavily coated areas is favored.

Following electrocoating, the work is rinsed and cured. Curing removes solvents and irreversibly alters some resins, improving coating finish. The technique is efficient in terms of energy and materials. This has led to a number of applications in large-scale processes, notably the priming of large metal parts such as car bodies prior to further spray coating. Electropainting is also used to coat coil stock, pipes, sheet steel constructions, and cans.

Commercial electropriming tanks use refinements such as ion-selective membranes around the counter-electrode to prevent diffusion of unwanted ions, and thus control paint pH (Fig. 28). The anodes in such systems are usually made of stainless steel, typically with a surface area about one-quarter that of a car body. The body is immersed in the paint, large tanks are required. Direct current at 50 – 500 V is commonly used to electrodeposit the primer layer. The requirement of large-scale processing equipment leads to electrocoating being used where a large number of parts need to be coated quickly and cheaply.

Electrophoretic techniques may also be used to codepositpolymer or ceramic particles within an electrodeposited metallic film. The inert particles (e.g., PTFE, alumina, silicon carbide, or diamond) can be dispersed in the electrolyte by high-stability (usually fluorocarbon-based) surfactants. The choice of surfactants and their concentration are critical in determining deposit properties and composition. Examples of the resultant "inclusion coatings" are Ni – PTFE, Co – SiC, and Ni – SiC.

1.7.4. Trends in Electrodeposition

Electroplating is vital in almost every branch of industry where the technique can provide a versatile and economic method of applying a thin

Figure 28. Cathodic priming of car bodies

An ion-selective membrane prevents diffusion of H^+ and controls pH.

(1 – 75 µm) metallic coating. However, itis essential to consider the effect of the shape, texture, and material composition of the workpiece at the design stage. Of the many modern developments in electrodeposition technology, several trends may be highlighted:

1) Electroplating of alloys of controlled composition, e.g., Ni – Fe or Pd – Ni as cheaper alternatives to single-metal coatings
2) Codeposition of metals with either polymers or ceramics to provide unique wear-resistant or "self-lubricating" coatings, e.g. Ni – PTFE, Ni – diamond, Co – WC, Zn – alumina
3) Electroless (zero-current) plating of an increasingly wide range of single metals, alloys, and composites, e.g., electroless Ni – P – PTFE
4) Low-temperature nonaqueous electrolytes for deposition of refractory metals, e.g., Ti, Ta, and Nb
5) Selective use of special, programmed current waveforms, e.g., periodic current reversal (rather than the normal steady direct current) in order to produce thick, dense, pore-free coatings, particularly for demanding electronic applications and severe wear-resistant applications
6) Selective, high-speed, automated electroplating processes for reel-to-reel plating of electronics materials
7) Local enhancement of deposition rates by use of laser irradiation, jetted electrolyte flow, as well as by acoustic, mechanical, or ultrasonic vibration
8) Development of polymer coatings based on electrochemical deposition from a monomer in the electrolyte, e.g., polypyrroles and polythiophenes whose conductivity can vary over many orders of magnitude via variation in monomer, electrolyte, and deposition conditions
9) Continued developments in electrophoretic deposition of polymers and ceramics, particularly in the finishing of car bodies

Journals and Periodicals. The electrochemistry of electrochemical deposition reactions is considered in the following journals:

Journal of Applied Electrochemistry
Journal of Electroanalytical Electrochemistry
Journal of the Electrochemical Society
Electrochimica Acta
Soviet Electrochemistry
Bulletin of Electrochemistry

Journals devoted to aspects of the surface finishing of metals include:

Plating and Surface Finishing
Metal Finishing
Transactions of the Institute of Metal Finishing
Galvanotechnik
Oberfläche-Surface
Metal Finishing (India)

Other journals relevant to the electrochemical deposition of thin films include:

Surface Technology
Thin Solid Films
Synthetic Metals

2. Thin Films as Materials

For a discussion of corrosion-resistant coatings → Steel, Chap. 5.3., → Steel, Chap. 5.4., → Corrosion, Chap. 5.1.2.3..

2.1. Coatings for Electronic Applications

2.1.1. Introduction

The world market of semiconductor-related products increased from $\$45\times10^9$ in 1988 to $\$74\times10^9$ in 1993. The corresponding market for deposition equipment increased from $\$0.9\times10^9$ in 1989 to $\$1.5\times10^9$ in 1992. The worldwide hybrid market was estimated at $\$5.5\times10^9$ in 1990.

As microelectronics pushes the deposition processes toward shorter cycle time, higher reproducibility, uniformity/conformality, and lower cost, deposition processes have become highly sophisticated. For integrated circuit (IC) assembly, thin film multichip modules are of increasing importance [80], but are not discussed here.

2.1.2. Hybrid Technology

One of the oldest applications of thin films in electronics are carbon resistors deposited on cyclindrical ceramic substrates by pyrolysis of a mixture of hydrocarbons at 400 – 600 °C. Because of the high negative temperature coefficient of resistivity (TCR) and the high tolerance of the resistance (± 10 – 20 %) metal resistors (base materials: NiCr, TaN, or CrSi) are now dominant [81]. In R – C networks the negative TCR of the resistor is compensated by the positive TCR of the capacitor [82]. Thin film hybrids are at present only a small portion of the hybrid market, but their share is likely to grow because large-scale integration for multipole ICs requires thin film memories, microprocessors, logic devices, semicustom, linear and discrete components, and also because higher pin-in/pin-out counts for dense modules are now achievable.

2.1.3. Microsystems

Combining micromachining technology of Si [83] with data collection (sensors) and microelectronic data processing has created a new class of products called microsystems (intelligent sensors).

Infrared sensors are made of HgCdTe or GaAs. For HgCdTe deposition, a lot of effort has been put into vapor-phase deposition, because of the performance-limiting defects which occur with epilayers. The range of detectable wavelengths can reach 8 – 12 µm.

Optical sensors/detectors consist of Si deposited by evaporation, sputtering or CVD. Applications include scanning, colorimetry, position sensing, fiber optic sensing, multiplexing, and bar-code reading.

Gas sensors are made of doped Si or polymers. Applications include smoke detectors, detection of trace quantities of toxic gases, and combustion control for car engines.

Pressure sensors employ NiCr, Si, piezoceramics (e.g., ZnO), GaP, or heterostructures. They are used in strain gauges, pressure sensing, acceleration sensing, and microphones.

2.1.4. Data Storage

Thermal print heads [84] are fabricated from highly resistive, highly stable compounds with low TCR, e.g., CrSiO, TaN, or HfN as heating elements; SiO_2 or Si_3N_4 for wear protection. They are used in facsimile machines, barcode printers, industrial printers and dye-transfer printers. For bubble-jet print heads and magnetic record heads see [85, 86].

Magneto-optic (MO) storage. In MO storage [87] the Kerr effect is used for data storage and reading. The materials used are generally amorphous alloys of rare earths and transition metals (Fe, Co) deposited by sputtering. These amorphous materials do not suffer from "grain noise".

2.1.5. Microelectronics

The two most important physical processes in microelectronics materials preparation do not

involve deposition. Diffusion/ion implantation is used for the local, electrical activation of the bulk Si, and thermal oxidation produces the high-performance gate oxides [88]. Nevertheless, for a 16 megabit dynamic random access memory, about 20 deposition processes are needed (two-level metallization with W contact hole-filling). Before depositing the first metallization layer [sputtered Al – Si (1 wt %) or Al – Si (1 wt %) – Cu (0.5 – 2 wt %)] deposition temperatures above 450 °C may be applied.

High-Temperature processes. Applications include insulation (capacitor dielectrics):

$$SiH_2Cl_2 + 2N_2O \xrightarrow{910\,^\circ C} SiO_2 + 2HCl + 2N_2$$

oxidation masking (capacitor dielectrics):

$$3SiH_2Cl_2 + 7NH_3 \xrightarrow[40\ Pa]{750\,^\circ C} Si_3N_4 + 3HCl + 6H_2 + 3NH_4Cl$$

and formation of conformal insulation layers, spacers, etch-stops, and protection against dopant out-diffusion:

$$\underset{\text{(TEOS)}}{Si(C_2H_5O)_4 \text{ at } 30-70\,^\circ C} \xrightarrow{700\,^\circ C} SiO_2 + 2H_2O + 4C_2H_4$$

Medium-Temperature Processes. Applications include the use of BPSG (Boron – phosphorus – silicate glass) for insulation, smoothing of edges, and planarization of topography by a 850 – 900 °C anneal/flow step:

$$Si(C_2H_5O)_4 + B(OCH_3)_3 + PH_3 + (O_2) \xrightarrow{630-680\,^\circ C} \text{BPSG + decomposition products}$$

This process is hard to control under production conditions and new processes have been developed [89].

Another application is the production of conduction lines:

$$SiH_4 \xrightarrow[40\ Pa]{630\,^\circ C} Si + 2H_2$$

This CVD process is important in semiconductor technology, and has influenced the development of equipment (tube furnaces, low-pressure CVD). The process gives high-purity deposited polycrystalline Si and high throughput (ca. 100 150-mm wafers per hour) and gives outstanding uniformity and conformality of the film thickness.

The resistivity of doped poly-Si is too high for some applications, and a new class of materials has been introduced (refractory disilicides: $TiSi_2$, $MoSi_2$, $TaSi_2$, WSi_2) which are in equilibrium with Si at higher temperatures. The films are sputtered from compound or mosaic targets.

Metallization Processes [90, 91]. For the electrical connections between activated areas, an alloy of Al – Si (0.5 – 2 %) is sputter deposited. The low-cost Al reduces the native silicon oxide at ca. 450 °C, leading to low ohmic contact resistances. The Si content in the alloy avoids pronounced out-diffusion of the bulk Si into the Al conduction line. After cooling, the Si alloy component forms lightly doped precipitates, preferably on the bulk Si, with average diameter 0.3 – 1.5 µm.

For sub-micrometer technology, TiN or Ti – W – N layers are applied to reduce Si precipitates in the contact holes. Since these barrier layers have excessive contact resistance to Si, an additional contact layer (e.g., 50 nm sputtered Ti) is necessary. A further problem is that the step coverage of the sputtered films is no longer sufficient. Therefore CVD processes have been developed for TiN deposition [92]:

$$Ti[N(CH_3)_2]_4 + 2H^* \xrightarrow[40\ Pa]{430\,^\circ C} TiN + 3C_2H_6 + 2CH_4 + {}^3\!/_2 N_2$$

(where H∗ is produced by microwave irradiation) and for contact hole filling with W [93]:

$$WF_6 + 3H_2 \xrightarrow[8\ kPa]{430\,^\circ C} W + 6HF$$

Passivation. *Low-temperature plasma CVD processes* include:

$$3SiH_4 + 4NH_3 \xrightarrow[30\ Pa]{300\,^\circ C} Si_3N_4 + 12H_2$$

for compressive stress $10^8 - 10^9$ Pa, and:

$$3SiH_4 + 2N_2 \xrightarrow[0.5\ kPa]{390\,^\circ C} Si_3N_4 + 6H_2$$

for compressive stress 5×10^7 Pa. This is used for protection against alkali and H_2O diffusion.

In *multilevel metallization*, the Al – Si – Cu conduction line levels have to be separated by an intermetal insulating layer deposited by PECVD below 430 °C.

$$Si(C_2H_5O)_4 \xrightarrow[1.3\ kPa]{400\ °C} SiO_2 + \text{decomposition products}$$

For further developments see [94].

2.1.6. Semiconducting Films

The basic process for *thin film transistors* (TFTs) is the PECVD deposition of amorphous Si (a-Si) at 300 – 400 °C, starting from SiH_4. Many substrates are in use, e.g., Si, GaAs, glass, quartz, and alumina. The breakthrough was reached when doping of the a-Si by a simple codecomposition of *p*- and *n*-type dopant gas species (e.g., PH_3, B_2H_6) became possible. Applications include television, logic circuits for image sensors (CCDs), printer/copiers, and active matrix liquid crystal displays.

Polycrystalline Si TFTs seem likely to become an important competitor with a-Si for displays, because the drive electronics can be fabricated directly on the glass substrate during the formation of the TFT array.

In the field of *photovoltaics*, a-Si solar cells and GaAs, InP, CdTe, and $CuInSe_2$ cells are fabricated. GaAs and InP cells are attractive for use in space because of their high efficiency and radiation resistance. The efficiency of solar cells is limited by recombination of electrons at the transparent conductive oxide – *p*-layer interface; thin film materials such as ZnO, SnO_x and indium oxide – tin oxide (ITO) are under investigation [95].

Optoelectronic devices [96] are made from $LiNbO_3$ or polymers [97]. Applications include phase modulators, amplitude modulators, splitters, polarizers, and switches.

GaAs and GaAlAs [98] can also be used for detectors, waveguide components, and high-speed electronic circuitry on the same substrate. Thin film deposition processes promise to play a major part in integrated optics, e.g., semiconductor planar waveguides could be used to integrate several optical components with associated waveguides on a single substrate.

For the use of semiconductor superlattices grown from III – V, II – VI, and IV – VI compounds for quantum wells see [99].

2.1.7. Ferroelectrics [100]

Ferroelectrics can be made from: perovskite compounds, e.g., $BaTiO_3$, $KNbO_3$, $K(Ta, Nb)O_3$, $PbTiO_3$, $Pb(Zr, Ti)O_3$; or non-perovskite compounds, e.g., $LiNbO_3$, $Bi_4Ti_3O_{12}$, $(Sr, Ba)Nb_2O_6$.

The breakthrough for this multifunctional class of materials was an improvement of the deposition process [101]. For optical applications of ferroelectric films, the system technologies are not completely mature. Several alternative materials and device technologies exist. For electronic applications, ferroelectrics have commercial potential, e.g., in nonvolatile memories and dynamic random access memories, microactuators, thin film capacitors, and surface acoustic wave devices.

2.2. Hard and Decorative Nitride and Carbide Coatings

2.2.1. Introduction

Transition metal nitrides and carbides exhibit characteristics of covalent, ionic, and metallic bonding. They have high thermal and electrical conductivities while the covalent nature gives rise to high mechanical microhardnesses, typically 20 – 30 GPa [102, 103]. They exhibit a metallic luster, and for some compounds (e.g., TiN, VN, ZrN, TaC) interband transitions locate the reflectance edge in the middle of the visible region, giving a golden color. Most of the compounds are also completely soluble in each other, making it possible to tailor the properties by depositing carbonitrides, alloy nitrides, or alloy carbides [102, 104]. The combination of high thermal and electrical conductivities, hardness, and attractive color have resulted in extensive use as both wear-protective and decorative coatings. Nitride thin films are also used as diffusion barriers in integrated circuits.

2.2.2. Growth Techniques

Nitride and carbide coatings are grown by chemical vapor deposition (CVD) or ion-assisted physical vapor deposition (PVD). In the for-

mer, substrate temperatures > 900 °C are typical; in the latter, growth temperatures of 300–550 °C are common. For acceptable quality of coatings grown by PVD at 300–550 °C, ion bombardment is necessary during growth, usually by plasma-assisted techniques, e.g., magnetron sputtering, arc evaporation, or ion plating [104]. Owing to the nonequilibrium nature of PVD techniques, film microstructure and morphology, stress levels, hardness, adhesion, etc. depend strongly on the deposition conditions, and a large spread in properties is common for coatings prepared in different equipment [103]. The most systematic correlations between deposition parameters, microstructures, and properties are found for TiN coatings.

2.2.3. Coating Microstructures

The detailed microstructure of the coatings depends strongly on growth parameters, but under most conditions columnar microstructures are formed. Films grown by PVD at < 500 °C are low-density coatings with a pronounced columnar microstructure [105]. The columns extend from the substrate surface to the top surface (Fig. 29). The surface is typically rough with faceted columns. For dense films, temperatures significantly higher than 500 °C are required, but even in this case the microstructure is columnar. By using ion irradiation during growth, dense films can be grown, even below 500 °C. Ion bombardment enhances adatom mobility, forward sputtering, and recoil implantation, leading to densification [106]. The energy required to obtain dense films depends on growth conditions, but for typical growth rates of the order of μm/h and ion current densities in the mA/cm^2 range, ion energies of 50–100 eV are required [104–107].

As the ion energy is increased above that required for creating dense films, ion-induced defects (point defect clusters, small dislocation loops, sputtering gas atoms) become trapped within the film. This can lead to continuous renucleation during growth and interruption of the columnar microstructure (Fig. 30). A relatively smooth surface is obtained. As the microstructure changes from a porous columnar structure to a dense noncolumnar structure, the stress in the coatings changes from tensile to compressive. The compressive stress usually increases to a saturation value as the ion energy is increased [107]. Compressive stress levels as high as 10 GPa can be obtained. Thermal stresses due to different thermal expansion coefficients of substrate and coating are usually smaller than growth-induced stresses, unless temperatures significantly above 500 °C are used. The different microstructures are reflected in the physical properties of the coatings. For TiN hardness values of 10–40 GPa are reported [103] (the single-crystal bulk value for TiN is 20 GPa [102]). The lowest values are obtained for low-density films, the high-

est values only for coatings with high compressive stress levels. For optical or decorative purposes, low-density films with rough surfaces are not acceptable since their properties change with time and they are very sensitive to fingerprints. For most applications, dense, moderately compressively stressed coatings are required.

Grown with substrate at a negative potential of 150 V, i.e., intentional ion bombardment.

2.2.4. Adhesion

Since coated tools are subjected to very large forces, the adhesion strength between the coating and the substrate has to be very high. Although the available empirical results do not dictate a unique mechanism for adhesion-enhancing processes, some general requirements for good adhesion can be noted. The most important is to eliminate contamination of the substrate surface prior to growth. During high-temperature growth (e.g., CVD) organic contaminants are readily desorbed from the surface. High temperature also produces interdiffused graded zones between film and substrate, with strong metallurgical bonding, and thus a high adhesion strength (provided no brittle phase is formed). For low-temperature growth, in situ sputter etching in a noble gas (most commonly Ar) plasma is necessary [108]. In addition to removing surface contaminants, sputter etching avoids low nucleation density, since lateral growth may result in interfacial voids. During low-temperature PVD growth, graded interfacial zones can be formed by depositing interfacial layers. For TiN coatings, it is common to use Ti interlayers to promote adhesion [108, 109]. Collisional mixing by ion bombardment can also be used to create graded interfaces, and thus higher adhesion strength.

2.2.5. Hard Coatings

Nitrides. The most used and studied material for hard and decorative coatings is TiN [103, 110]. Stoichiometric bulk TiN has a hardness of 20 GPa and a golden color. However, owing to the wide stability range ($0.6 < N/Ti < 1.2$) its properties vary with composition [102]. The color can range from that of metallic Ti to almost brown. The different microstructures obtainable give coatings with a hardness range of 10 – 40 GPa. The majority of commercially used TiN films have compositions close to stoichiometric, hardness 20 – 27 GPa, and compressive stresses of a few GPa. For N/Ti ratios below 0.6, films consisting of both the NaCl-structure δ-TiN phase and the α-Ti phase are reported. Only in a few cases has the tetragonal ε-Ti_2N phase been reported in films grown from the vapor phase [111]. These usually have high compressive stress values and they have not yet found any commercial use. The exact phase composition is given by the kinetic conditions during growth.

Other common nitrides are the group 4 nitrides ZrN and HfN, both of which have properties similar to those of TiN. Bulk HfN has been reported to have a higher hot-hardness than TiN, and has been claimed to be beneficial in high-temperature applications, but so far HfN films have not been used in commercial wear-protective or decorative applications.

Except for CrN, transition metal nitrides from groups 5 and 6 are not used for wear-protective or decorative purposes.

Alloy Nitrides. Most transition metal nitrides are completely soluble in each other, making it possible to vary the properties of the coatings over a large range. The most studied alloy nitride is $Ti_{1-x}Al_xN$ [112]. Even though the NaCl-structure TiN and the

wurtzite-structure AlN are not mutually soluble, metastable $Ti_{1-x}Al_xN$ films with NaCl structure can be grown for $0.4 < x < 0.6$, depending on the growth conditions [113]. For growth of such metastable phases it is necessary to use strong kinetic limitations, through low growth temperatures, high growth rates, or ion-induced collisional mixing during growth. The metastable $Ti_{1-x}Al_xN$ phase decomposes above 900 °C to TiN and AlN [114].

$Ti_{0.5}Al_{0.5}N$ has a much higher oxidation resistance than TiN, owing to the formation of a protective Al-rich oxide layer, beneficial for high-temperature applications [114]. The oxidation temperature for $Ti_{0.5}Al_{0.5}N$ and a few other hard coatings are as follows [104]:

Coating	Oxidation temperature °C
TiC	400
TiN	550
CrN	700
$Ti_{0.5}Al_{0.5}N$	750
$Cr_{0.5}Al_{0.5}N$	910

The possibilities of using alloy nitrides to increase the oxidation temperature is clearly demonstrated. The structural and mechanical properties of $Ti_{1-x}Al_xN$ are similar to those of TiN. The electrical and optical properties depend on the Al content (the color changes from golden to dark violet as x is increased from 0 to 0.5).

Carbides. The hard carbide coatings used resemble those of nitride hard coatings, i.e., carbides from group 4 (TiC, ZrC, and HfC) dominate. Also, B and Si carbides have been studied for wear-protective applications. The structures of the transition metal carbides resemble those of the corresponding nitrides; all monocarbides in groups 4 and 5 have a B 1-NaCl structure. The hardness of the carbide is in general higher than that of the corresponding nitride (more pronounced covalent bonding) [102, 103]. Compared with nitrides the growth process is more complex (possibility of C precipitation as the C/metal ratio approaches 1, caused by the complex cracking patterns and chemisorption behavior of the hydrocarbon precursors). As free C precipitates, the film structure changes drastically to porous films with very small grain sizes [103].

Carbonitrides. Since most transition metal carbides and nitrides are completely soluble in each other, carbonitrides are sometimes used. As in the case of alloy nitrides, the properties can be varied continuously from those of the carbide to those of the nitride. Only TiCN coatings have been studied to any significant degree [103].

Multilayers. By using multilayers of different materials it is possible to take advantage of the characteristic features of each material and to obtain synergetic effects [115, 116]. The main reasons for using multilayers of nitrides and carbides are to facilitate strong adhesion, to obtain wear-protective films with low chemical reactivity and low friction, and to increase strength and hardness. Multilayers of the type $TiN/Al_2O_3/TiC$ deposited on cemented carbide substrates by CVD are used routinely in order to optimize adhesion and wear properties on cutting tool inserts [110].

By depositing nitride multilayer films with individual layer thicknesses of a few nanometers, significantly increased hardness values have been reported for films with total thicknesses of a few micrometers [115–122]. Examples of systems with hardness more than twice that of the individual materials include TiN/VN [117], TiN/NbN [118], and $TiN/V_{0.6}Nb_{0.4}N$ [119]. Figure 31 shows the variation in hardness for TiN/VN and TiN/NbN multilayers as a function of the multilayer wavelength Λ (the sum of the individual layer thicknesses). The enhanced

Figure 31. Vickers hardness of TiN/VN (open squares) and TiN/NbN (full squares) multilayers as a function of modulation wavelength [122]
Total film thicknesses 2.5 – 3 µm in both cases; hardness values for $\Lambda = 0$ nm correspond to the TiVN and TiNbN alloy values.

hardness can be explained by hindrance of dislocation motion across the layer interfaces (different dislocation line energies in the two materials) and by coherency strain [119]. Metal/nitride multilayers such as Ti/TiN, Hf/HfN, W/WN [121], and Ti/BN [122] have very high hardness values.

2.3. Carbon Films (General references [123–128])

2.3.1. Carbon Phases: Composition and Stability

Diamond and graphite are well-defined, long-range-ordered crystalline allotropes of carbon, that occur naturally. Structure, properties, and quality of vapor-deposited thin film variants are best judged by comparison with their natural equivalents. Other carbon phases are less well defined. They do not occur naturally, but are grown as thin films by chemical and physical vapor deposition (CVD and PVD) methods. Composition and properties of these phases depend strongly on the preparation conditions. Resulting differences are manifested by a confusingly long list of names: amorphous hydrogenated carbon (a-C:H), amorphous carbon (a-C), ion-beam-deposited carbon (i-C), mass-selected ion-beam-deposited amorphous carbon (MISB a-C), tetrahedral amorphous carbon (ta-C), and diamond-like carbon (DLC). DLC is also frequently used for the whole class of amorphous carbon phases. They may contain considerable quantities of hydrogen, varying amounts of sp^3- and sp^2-hybridized carbon atoms. The ternary phase diagram (Fig. 32) is a convenient way to display the compositional differences [129, 130], to correlate them with different properties, and to outline the relation between the various carbon phases. The sp^2-vertex represents graphite, a hydrogen-free crystalline material that consists of aromatic carbon layers built from threefold-coordinated sp^2- carbon atoms. The sp^3-vertex corresponds to diamond, hydrogen-free, cubic crystals formed by exclusively covalently bound, fourfold-coordinated sp^3- carbon tetrahedra. Noncrystalline, hydrogen-free carbon phases, called either a-C or, with more than 80 % sp^3- carbon, ta-C, are located on the sp^2 – sp^3 side line. Films with a C – C skeleton are feasible only up to a certain level of hydrogen in the solid. At higher H concentrations films do not form (Fig. 32, dashed line [130]). The compositional coordinates of the various carbon thin films in Figure 32 determine whether their physical properties are closer to diamond (high sp^3-C, low H content), to graphite (high sp^2-C, low H content), or more like polymers (high H content).

Figure 32. Ternary sp^3-C/sp^2-C/H diagram for carbon films ([129, 130], modified)

Of all the carbon phases mentioned, only graphite is thermodynamically stable. All other carbon phases are metastable, and, although reasonably stable for many applications at room temperature, convert to graphitic material on heating in an inert atmosphere. While a-C:H and a-C change their structure at 300 – 600 °C [131], ta-C seems to tolerate more than 1000 °C [132]. Diamond graphitizes rapidly at temperatures > 1500 °C [124, 128]. Composition, structure, and stability define the physical and chemical properties of the films and, along with the deposition temperature, define their application areas.

2.3.2. Properties and Applications of Diamond Films

There is no other material with such a combination of properties as diamond. It is the hardest of all materials. At room temperature, it has the highest thermal conductivity. Diamond is transparent from the UV to the microwave region of

Table 9. Properties and applications of diamond films

Property		Comparison with competitors	Possible applications
Indentation hardness, kg/cm^2	10 000	β-BN < 4500; SiC < 4000; WC = 2190; steel = 800	drill bits, polishing material, cutting tools
Coefficient of friction	0.05 – 0.1 (only in air)	PTFE ≈0.05	ultra-low-wear coatings
Young's modulus, GPa	1050	2× the value of alumina; 5× that of steel	stiff membranes for lithography masks, lightweight diaphragms for audio devices
Sound propagation velocity, km/s	18.2	1.6× the value of alumina	
Chemical inertness	oxidation at T > 600 °C	at room temperature, resistant to all acids, bases and solvents	coatings for reactor vessels
Range of high transmittance, µm	0.22 – 3 and>6	in the IR orders of magnitude lower than most other materials	UV – vis – IR windows and coatings, microwave windows, X-ray windows (low Z)
Refractive index	2.41	1.6× the value of silica	
Band gap, eV	5.45 (negative electron affinity)	1.1 for Si; 1.43 for GaAs; 3.0 for β-SiC	high-power/high-temperature electronics, e.g., thermistors, transistors, particle detectors, cold cathodes for displays, vacuum microelectronics
Electron/hole mobility, cm^2 V^{-1} s^{-1}	1900/1600	1500/600 for Si; 8500/400 for GaAs	
Dielectric constant	5.5	11 for Si; 12.5 for GaAs	
Thermal conductivity, W m^{-1} K^{-1}	1300 – 2200	highest at room temperature; 4× the value of Cu or Ag	heat sinks, heat spreaders
Thermal expansion coefficient, K^{-1}	0.8×10^{-6}	at room temperature, similar to silica (0.57×10^{-6})	thermally stable substrates, e.g., for X-ray lithography masks

the spectrum (except for a small gap between 3 and 6 µm). It is an excellent insulator, but can be doped and converted into a low-resistivity semiconductor. Diamond is chemically inert at room temperature and, owing to its high atom density, is extremely rigid. The properties of the best vapor-grown diamond films are identical with those of natural diamond. Significant differences between natural and vapor-grown material result from the polycrystalline structure of the latter. Polycrystalline diamond films usually exhibit a columnar growth morphology with crystal grains of 0.1 to> 100 µm. The grain boundaries tend to be decorated with contaminants and, depending on the deposition conditions and process, anything from black films with considerable amounts of non-diamond carbon phases, other impurities (Si, O, etc.) and several percent hydrogen, to transparent material with less contamination than natural diamond, is feasible. Table 9 lists the physical properties of diamond, in comparison with some competing materials and possible applications of vapor-grown diamond films.

Mechanical Properties and Applications. The hardness and wear resistance of diamond and its resulting application as a material for tools and abrasives is common knowledge. Diamond CVD permits growth of polycrystalline films of at least comparable hardness and wear properties, but free of the cobalt binder that is required when compacting high-pressure diamond powder into tool bits. Binder-free, polycrystalline films have an advantage over single crystals. Cleavage planes are absent, because of the random orientation of crystallites. Grain boundaries prevent crack propagation and the material is tougher and mechanically isotropic. The Young's modulus of CVD diamond is identical to that of single crystals: 1050 GPa. The rupture strength of 10 – 20 mm diameter CVD diamond plates with thicknesses of 150 – 300 µm is ca. 1000 ± 200 MPa, a factor of two lower than for single crystals. The fracture toughness is 6 MPa m$^{0.5}$, higher than the 3.5 – 5 MPa m$^{0.5}$ value reported for single crystals. The test performance of thick CVD diamond plates is hardly affected by the surface morphology of top-quality material, i.e., unpolished disks show the same values as polished material (for mechanical data see [133, 134]).

For films with thicknesses< 50 µm, the phase purity and hence all film properties depend strongly on the thickness. Vapor-grown, free-standing (substrate-free) diamond plates can be used as single-point tools or, if brazed onto a tool insert, can replace high-pressure synthetic poly-

crystalline diamond compacts, i.e., in turning, milling, drawing, or bonding tools [135]. Diamond can also be directly deposited onto various tool materials, e.g., tungsten carbide or SiAlON inserts. With appropriate surface treatment, the adhesion of such films is sufficient for practical applications. Coated tools require a minimum of diamond. A $< 10\,\mu m$ thick film is usually sufficient. They perform as well or better than conventional diamond tools, without their size limitations and often at a lower price [135]. Owing to the complex shapes required, directly deposited diamond layers are specially suitable for drilling tools [135]. The excellent mechanical properties are also required for other diamond applications, e.g., as high-pressure or vacuum windows.

Optical Properties and Applications. Type IIa natural diamond is optically transparent from its band edge at $0.220\,\mu m$ to ca. $3\,\mu m$. The lattice vibrations of diamond are excited between 3 and $6\,\mu m$, hence diamond is weakly absorbing in this region. At higher wavelengths it transmits electromagnetic radiation up to the microwave region of the spectrum [124, 128]. Figure 33 sketches the optical transmission spectra of diamond and other common optical window materials, e.g., LiF (UV windows), silica (visible), and CsI (IR) [136]. Transmission losses of 31 % for diamond are due to reflections at two diamond – air interfaces (refractive index ca. 2.41). The best quality CVD diamond films are now approaching the characteristics of type IIa natural diamond [137]. Problems are related to:

1) Excess absorption between 220 and 350 nm, owing to nitrogen incorporation in the solid
2) Excess absorption between 220 nm and $3\,\mu m$, owing to non-diamond carbon phases
3) Scattering losses due to the surface roughness of the polycrystalline structure (affected wavelength region depends on grain size)

While excess absorption can be avoided by contamination-free deposition procedures, scattering at the rough growth surface is inherent to polycrystalline material. Either by polishing (for thick diamond plates) or by deposition of very fine-grain material (suitable for thin films and membranes), scattering in the visible region can be minimized. For top-quality material, the grain boundaries inside thick polished plates hardly affect the transmission properties.

Figure 33. Optical transmission spectra for diamond and other optical window materials [136]
a) LiF; b) Silica; c) CsI; d) Diamond

Vapor-grown diamond films and plates can be used as windows for electromagnetic radiation of any kind. With its unique combination of mechanical strength, chemical inertness, high transparency, and low atomic number, diamond is particularly useful in harsh environments and as a protective optical coating for sensitive materials such as IR optics.

Thermal Properties and Applications. At room temperature, diamond is the best thermal conductor available; at 20 °C, values of 2000 – 2200 $W\,m^{-1}\,K^{-1}$ were measured for type IIa natural single crystals – four times the value of copper or silver. The thermal conductivity of diamond peaks at ca. 65 K with values around 17 000 $W\,m^{-1}\,K^{-1}$. Between room temperature and 500 °C, the thermal conductivity κ decreases, following the empirical formula [138]:

$$\kappa = 27\,350\,T^{-1.26}$$

Top-quality material has conductivity ca. 700 $W\,m^{-1}\,K^{-1}$ at 500 °C, still twice the value of copper or silver (Fig. 34). The transport of thermal energy in diamond is a phonon-coupled phenomenon. Despite the polycrystalline nature and the numerous grain boundaries that could disturb phonon propagation, CVD diamond films with the thermal properties of the best natural single crystals have been produced [137–140]. Film thicknesses $> 100\,\mu m$ with grains larger than $20\,\mu m$ are required to obtain values above 1800 $W\,m^{-1}\,K^{-1}$. Thin films suffer from contamination by excess non-diamond carbon phases and from phonon scattering at the

grain boundaries of numerous small ($< 5\,\mu m$) crystals. For $4\,\mu m$ thick films, values of ca. $700\,W\,m^{-1}\,K^{-1}$ are feasible [140]. Isotopically enriched ^{12}C-diamond single crystals as well as films exhibit a thermal conductivity 20 – 50 % higher than that of natural (99 % ^{12}C) material [141].

Figure 34. Temperature dependence of the thermal conductivity of diamond and other commonly used heat spreader materials
a) Type IIa natural and best quality CVD diamond; b) Cu; c) BeO; d) AlN; e) Al_2O_3

In addition to its extremely high thermal conductivity, diamond has a very low thermal expansion coefficient, $0.8\times10^{-6}\,K^{-1}$ at room temperature. However, this value applies only to single crystals and top-quality thick CVD diamond plates. Non-diamond carbon contamination in thin films may increase the values to $> 2\times10^{-6}\,K^{-1}$.

The application of high-thermal-conductivity diamond as a highly efficient heat spreader for high-power electronic devices and high-thermal-load laser windows is well established. CVD films make it possible to overcome the cost and size limitations imposed by the use of natural single crystals and may compete in applications currently served by poisonous BeO or AlN.

Electrical Properties and Applications. Pure diamond is electrically insulating with resistivity $> 10^{11}\,\Omega\,cm$ and breakdown electrical field 10^7 V/cm, which is similar to silica [124, 128]. The values for polycrystalline films are lower [136] and depend on the thickness. Again, grain boundary decoration with non-diamond carbon phases poses a problem and only ultra-pure CVD diamond approaches the breakdown voltage values of single crystals. The resistivity of diamond can be modified either by UV illumination or by doping with boron. For both natural boron-doped crystals and vapor-grown films, resistivities < 0.1 to $100\,\Omega\,cm$ are feasible. Boron-doped diamond is a *p*-type semiconductor with activation energy ca. 0.38 eV [136, 142]. The feasibility of true *n*-type doping of diamond with significantly low resistivity is still under discussion. Phosphorous, nitrogen, or lithium are possible *n*-type dopants. Implantation of C^+ may also lead to *n*-type conductivity. In all cases, the material is still highly resistive and $p-n$ junctions are not yet feasible. The carrier mobilities in undoped bulk diamond are $2200\,cm^2\,V^{-1}\,s^{-1}$ for electrons and $1600\,cm^2\,V^{-1}\,s^{-1}$ for holes [124, 128]. The polycrystalline nature of CVD diamond severely affects the mobilities. For randomly oriented boron-doped material, carrier mobilities $< 50\,cm^2\,V^{-1}\,s^{-1}$ are common. At room temperature, highly oriented (100)-textured boron-doped films exhibit values of $300-400\,cm^2\,V^{-1}\,s^{-1}$ and for homoepitaxially grown boron-doped films 800 – $1000\,cm^2\,V^{-1}\,s^{-1}$ has been reported [142]. Device operation fieldeffect transistor, FET at 300 – 600 °C is feasible. For (100)-oriented boron-doped films, the carrier concentration increases from $10^9\,cm^{-3}$ at room temperature to $10^{16}\,cm^{-3}$ at 500 °C. Unfortunately, the hole mobility was found to drop from $350\,cm^2\,V^{-1}\,s^{-1}$ at room temperature to $120\,cm^2\,V^{-1}\,s^{-1}$ at 500 °C [142]. The properties of CVD diamond now allow the construction of the first high-power, high-temperature electronic devices (e.g., transistors, diodes, and sensors). Tremendous progress has been made over the past decade: prototype devices operating at 500 °C are available and the first logic circuits [143] have been demonstrated. However, to implement a diamond-based semiconductor technology still needs a lot of work.

Diamond is not only interesting as an active device and sensor material, but has unusual electronic surface properties which might be exploited in cold cathodes. The (111) surface of natural boron-doped diamond was found to exhibit "negative electron affinity" (NEA) [144]. This means that the energy level of the conduction band of diamond is slightly higher than

that of electrons in vacuo. NEA materials emit electrons once they are excited across the band gap (5.45 eV for diamond) by, e.g., UV light or high electric fields into the conduction band. Diamond might, therefore, serve as a cold electron source for various applications, e.g., flat panel displays. The NEA properties depend strongly on the surface state of the diamond; H- and HO-terminated surfaces emit electrons while reconstructed diamond surfaces show no emission. CVD diamond films display NEA properties and large-area electron-emitting surfaces seem feasible.

2.3.3. Properties and Applications of a-C:H, a-C, and ta-C Films

Amorphous carbon phases are also called diamond-like carbon (DLC) films, referring to the hardness of some of these materials. Hardness, and the fact that the films are carbon-based, are about the only relationship between diamond and some members of the DLC family. Figure 32 illustrates that DLC usually consists of a mixture of sp^2- and sp^3-hybridized carbon and, depending on the preparation conditions, may contain up to 65 atom % hydrogen. The properties of the different DLC types depend strongly on the composition. They range from polymeric, soft, transparent, and insulating, to hard, dark, and conducting. In all cases the films are amorphous and the properties are isotropic.

Figure 35 correlates the hydrogen content, density, optical band gap, and hardness of DLC films grown under different deposition conditions, i.e., different bias voltages.

Mechanical and Chemical Properties and Applications. The hardness, low friction coefficient, and wear resistance are the most useful properties of some members of the DLC family. If deposited properly, a-C:H films can reach a density of 2.0 g/cm^3 and a hardness of 40 GPa (diamond: 100 GPa). The values for soft, hydrogen-rich a-C:H films and soft, sp^2-C-rich a-C are ca. 2 – 5 GPa. With 90 – 100 GPa and densities of 2.5 – 3.1 g/cm^3, mass-selected, ion-beam-deposited hard a-C are closest to diamond (see also Fig. 32). Unfortunately, the thickness of these films is limited by the high internal compressive stress [132].

Figure 35. Correlation of A) Hardness; B) Density; C) Optical band gap; and D) Hydrogen content of DLC films grown from benzene by r.f. plasma CVD at different bias voltages [130]

Friction coefficients < 0.1 are common for DLC. Like that of diamond, the coefficient of friction is very sensitive to humidity, but unlike diamond, it is reduced in dry air or vacuum.

Chemically, DLC films are inert to most acids and bases at room temperature. At higher temperatures they are attacked. Moreover (see the discussion of stability in Section 2.3.1) they

change their structure and ultimately turn into graphite films [130, 132, 145, 146].

Because of their excellent mechanical and chemical properties and the fact that it is possible to deposit DLC films at room temperature, they are widely used as protective, low-wear, low-friction, or antireflection coatings on, e.g., IR optics, sunglasses, magnetic recording disks, or metal film recording tapes. Although the properties are inferior to diamond, the low-temperature growth option is a big advantage of DLC films over diamond for such applications [146, 147].

Biomedical Properties and Applications. Carbon has been used for many biomedical applications. Tissue can adhere to it and a protein layer that forms on its surface prevents the formation of blood clots. The ideal solution for biomedical implants would be a combination of the mechanical strength of metals and the biocompatibility of carbon. DLC films deposited onto metal implants seem to provide this combination [146, 147].

Optical and Electrical Properties and Applications. The optical properties of DLC films are also highly dependent on the sp^2/sp^3 ratio and the hydrogen content. Films with a high hydrogen content are transparent in the visible with optical band gaps of up to 4 eV. Hard a-C and a-C:H films are less transparent with gaps of 1 – 2.5 eV. With a gap of 0.4 – 0.8 eV, soft, graphite-like a-C films are hardly transparent. The optical properties of DLC are often exploited in conjuction with the mechanical properties, e.g., in protective coatings for optical components [130, 145, 147].

Electronically, all DLC films are best described as composite materials, consisting of conductive, graphitic islands embedded in an insulating matrix. Like diamond, ta-C films show photoconductivity, however, white light is sufficient to change its conductance by two orders of magnitude at 125 K [132]. Doping with nitrogen changes this effect, and also effects the electrical conductivity of the material. Pure ta-C is a good insulator ($10^{-9}\ \Omega\,\mathrm{cm}$), N-doped ta-C is more conductive [132]. Doping of DLC films has been investigated, but device applications of DLC films, if any, are still in their infancy.

2.4. Metallic Films [148–160]

2.4.1. Introduction

Techniques for the preparation of thin films include: electrodeposition, hot dipping, cementation, diffusion, flame spraying, plasma spraying, laser coating, roll bonding, powder rolling, mechanical impingement, explosive bonding, chemical vapor deposition, physical vapor deposition, sputtering, and ion implantation. The properties of metallic coatings depend on the technique used and on the processing conditions; the last decade has seen the increasing use of dry techniques, such as vapor-phase deposition, which are becoming competitive with wet processing techniques in some areas of surface finishing.

Thin metallic films find extensive use in the electronics and engineering industries, as coatings on a substrate or as detached films (e.g., electroforming of foil or mesh). By selection of deposition technique and process conditions, it is possible to produce films in the range 0.1 – 20 μm of materials which include compact single metals and alloys, composite metal – polymer and metal – ceramic layers, conductive polymers, and solid-state ceramics and dispersed coatings of catalysts on a porous substrate (Table 10).

2.4.2. Electronics Applications

Thin metallic films may be used to alter the electrical properties of polymer, ceramic, and metal substrates, or the substrate may be viewed as a support for the production of a specific film. Examples include the metallization of laminates, such as glass-reinforced polyester and epoxy materials to produce printed circuit board tracks, switch contacts, and connectors. Following catalytic activation of the surface by a thin palladium deposit, copper may be deposited on a plastic printed circuit board laminate by electroless plating or by screen printing of copper-containing inks. The film may be thickened by electroplating of copper to produce conductive tracks. For edge connectors, further electrodeposition of nickel, then gold, is common, while solderability can be provided by the electrodeposition of tin – lead alloys. Porosity and adhesion problems require care in the formulation

Table 10. Thin film materials and their applications

Material	Typical film thickness, μm	Deposition technique	Applications
Zinc	75 – 100, 7 – 20, 20 – 40	hot dipping diffusion electroplating	corrosion protection of steel
Chromium	10 – 120	electroplating	corrosion- and wear-resistant coatings on steel
Copper	2 – 10	electroless plating, electroplating	conductive tracking
Gold	1 – 5	electroplating	electronic contacts
Copper, nickel, iron, Ni – Co	10 – 1500	electroforming	metal foils and flat meshes; audio and video disk stampers; waveguides; electric razor "foils" and liquid food filter meshes; molds for plastics; magnetic display boards (Ni and Fe)
Nickel – phosphorus	5 – 30	electroless plating	bearing and valve surfaces
Nickel – boron	5 – 30	electroless plating	high-temperature wear-resistant coatings
Dispersed platinum	(1 – 10 g/m^2)	electroplating, chemical deposition	fuel cell electrodes, electrolytic conductivity probes
Tin – lead	5 – 10	electroplating	solderable tracks on printed circuit boards
Cobalt – nickel – gold	2 – 10	electroplating	edge connectors on printed circuit boards
Nickel – silicon carbide	5 – 30	electroplating, electroless deposition	abrasive wheels and cutting tools
Nickel – PTFE	5 – 30	electroplating, electroless deposition	self-lubricating, non-stick coatings
Titanium nitride, titanium carbide	4 – 8	chemical vapor deposition, plasma deposition	wear-resistant cutting tools
Alumina	15 – 25	anodizing	corrosion-resistant coatings on aluminum
Tantalum oxide	1 – 8	anodizing	high-stability capacitors
Molybdenum disulfide	4 – 10	chemical vapor deposition	lubrication of internal combustion engine surfaces

of pretreatment sequences and rinses between coating stages. Conductive inks are cost effective and versatile for the formation of conductive tracks on printed circuit boards and for other applications (Table 11). They consist of a conductive pigment (metal flakes or particles), a binder (polymer resin), and a solvent or dispersant. The pattern is formed by forcing the liquid ink through a masked mesh or screen. The ink is then cured (usually by heat) to remove the solvent. The resin contracts, forcing the pigment particles together to produce a conductive coating. After curing, the coating thickness is usually 3 – 12 μm, although thicker coatings are possible. Conductive inks are printed onto a range of substrates, principally ceramics, printed circuitboards, and flexible plastics (e.g., polyester or polycarbonate). It is possible to electroplate metals onto some cured inks to increase conductivity and durability. By blending metal pigments it is possible to combine the properties of the constituent metals.

Table 11. Conductive inks and their applications

Substrate	Metal(s)	Applications
Ceramics	gold, silver, copper, silver – palladium blend	conductive tracking; capacitors
Printed circuit boards	silver, copper	conductive support for tracking
Flexible polymers	silver	conductive tracking; keyboards; switches; RFI∗ shielding; medical sensors; communications antennae
	copper	flexible printed circuits
	nickel	RFI shielding; magnetic shielding; environmental protection
	silver – carbon	environmental protection; chemical sensors; resistors; keyboards
	carbon – rubber	force-sensitive resistors
	silver – nickel	conductive tracking; magnetic conductors; phone cards
	iron oxides	magnetic cards, "smart" cards

∗ RFI = radiofrequency interference.

A variety of gas-phase techniques can be used to produce special materials. Reactive sputtering can produce compound semiconductor coatings of CdS by sputtering from a Cd target in an $Ar + H_2S$ atmosphere. The ability of sputtering to control coating composition makes it a useful technique in the electronics industry (metallization of aluminum alloy microcircuits, refractory metal microcircuits, optically transparent conducting electrodes, piezoelectric transducers, optically addressed memory devices, thin film resistors and capacitors, video disks, and thin film lasers). Sputtering can also produce

multilayer stacks of dielectric materials such as TiO_2, Ta_2O_5, Al_2O_3, and SiO_2, which are harder and denser than evaporated layers.

2.4.3. Engineering Coatings

As seen in Section 1.7.1, a wide range of single metals, alloys, and composites can be electrodeposited or electrolessly plated from aqueous solution. Examples include electroless nickel–phosphorous coatings for wear resistance on valves and corrosion protection, and chromium coatings for wear resistance under arduous conditions (hydraulic cylinders, gun barrels). Special applications include the use of Ni–PTFE inclusion deposits for carburetor butterfly valve spindles and the use of Co–WC as a wear-resistant coating for cutting tools.

In dry processing techniques, flame and plasma spraying can produce wear-resistant layers of materials such as stainless steel alloys, WC, Si_3N_4, SiC, and Al_2O_3. Sputtering, in combination with heating of the substrate (or the use of a reactive atmosphere) can produce hard, wear-resistant coatings such as titanium nitride. A 3-mm TiN film with hardness > 2000 Knoop/mm^2 can be produced for high-temperature hobs. Solid lubricants can greatly decrease wear, e.g., sputtered films of MoS_2 can have a coefficient of friction of ca. 0.04 against steel, with lifetime more than 100 times that of brushed-on MoS_2 films.

For some metals, a number of coating technologies are available and the choice depends on the environment and service lifetime, as well as cost. In corrosion protection, sacrificial coatings of zinc on steel may be produced by electroplating, hot-dip galvanizing, or high-temperature diffusion (Sheradising). Hot-dipped coatings have thickness 20–200 μm, the usual range being 70–100 μm. A series of Fe–Zn alloy layers are produced, the top layer consisting of pure zinc if a low-temperature process is used. The result is excellent adhesion and reasonable resistance to abrasion; this coating process may be chosen when arduous conditions are involved, a long lifetime is sought, or if no further coatings (e.g., paints) are to be applied. Zinc diffusion coatings are usually restricted to smaller workpieces, e.g., fasteners, metal brackets. The surface of the steel is converted to a film of iron–zinc alloys, in a batch process involving zinc powder at elevated temperature, with typical coating thickness 7–25 μm. The coating has reasonable abrasion resistance and uniformity, and is used when no further anticorrosion coatings are applied. For large-scale or continuous coating (e.g., steel coil or sheet) or for substrates that are deformed by high-temperature processes, electroplating of zinc (or an alloy with higher corrosion resistance, e.g., Zn–Ni, Zn–Fe, Zn–Co) is often used, as in car body panels. In electroplating, the films tend to have less toughness and resistance to abrasion, owing to the absence of intermetallic, alloy layers.

Zinc, aluminum, magnesium, and iron alloy surfaces can be chemically modified by a conversion coating to produce, e.g., oxides (anodizing of aluminum), chromates, and phosphates. Such treatments can significantly improve corrosion resistance and, in the case of phosphating, lubrication conditions can also be improved.

For noble coatings, e.g., electroless nickel, electroplated nickel, or chromium, the coating must have low porosity, as pitting of the underlying steel can occur at coating defects. The stress distribution and cracking pattern in chromium-plated layers is important in long-term performance, both for corrosion protection and tribology.

Gas-phase techniques have specialist uses in corrosion protection, e.g., ion plating to coat aircraft and spacecraft steel and titanium fasteners with aluminum. The aluminum layers have good uniformity, adhesion, strength, and mechanical properties, and have, in some cases, replaced cadmium electroplated layers (which tended to suffer from hydrogen embrittlement and stress cracking). Ion plating of aluminum is also used to coat thin-walled stainless steel heat exchanger tubes and interconnecting sections. Other applications include Cr, Al_2O_3, Si_3N_4, Cd, Ti, C, and Ta on steel for medical, biochemical, and industrial chemical applications.

2.4.4. Dispersed Catalytic Coatings

The majority of metallic films are compact, uniform-thickness layers on a nonporous substrate, but an important class of coatings are produced by dispersing a precious metal onto

a porous substrate, to produce a catalytically active, high surface area coating which uses a minimum of the costly coating material. Examples include:

1) Deposition of platinum or platinum alloys onto porous carbon paper, carbon cloth, or ionically conductive polymer membrane to produce porous gas diffusion electrodes. These are used in aqueous electrolyte fuel cells, speciality batteries using gaseous reactant (e.g., the aluminum – air cell), in electrochemical gas sensors, and as a hydrogen anode. The electrode surface must remain electrically conductive and act as a three-phase boundary at the interface of gases, liquid electrolyte, and solid catalyst, and it is common to control the wetting properties of the electrode to avoid flooding of the structure, by the use of PTFE which also acts as a binder.
2) The deposition of platinum-group metals and alloys onto porous metal and ceramic substrates to produce catalytic converters for car exhausts. The ability to recycle the expensive catalyst is an important consideration.

In both of these applications, there is a trend toward lower loadings of the precious metals. In fuel cell electrodes for phosphoric acid H_2/O_2 cells, the loading of platinum metal on carbon has decreased toward ≤ 1 mg/cm^2. Techniques to produce dispersed coatings include combinations of chemical impregnation, electrodeposition, and thermal treatment. More recently, sputtered and other vapor-phase-technology coatings have been considered, although they are much more costly than chemical impregnation followed by heat treatment.

2.4.5. Developments and Trends

The range of thin metallic films continues to increase as more advanced techniques are implemented and new alloy, polymer, and composite coatings are explored:

1) Increasing use of vapor-deposition techniques, particularly chemical vapor deposition and ion implantation, to produce very thin, nonporous layers for the electronics and engineering industries
2) Introduction of multilayer coatings by a number of different techniques or the alteration of process conditions during the application of a single technique
3) Increasing use of polymer, alloy, and composite coatings
4) Development of conductive polymer films with electrical conductivity ranging from that of an insulator to about one-tenth the value of some metals
5) Increasing need to use thin films of precious metal catalysts on a less costly, engineered substrate (fuel cell electrodes, specialized gas sensors, and car catalytic converters)
6) Development of cost-effective, environmentally attractive techniques for selective deposition of thin films (ion plating, laser or jet electroplating, and screen printing by jet techniques)
7) Formation of thin diffusion coatings by ion implantation

2.5. Superconductive Coatings

Since the discovery of high-temperature oxide superconductors [161], coatings (deposition and/or thin film growth) of several cuprates with a superconducting transition temperature T_c above liquid nitrogen temperature, 77.3 K, have been developed. Among the many high-T_c oxide materials synthesized to date, representative thin film materials for practical use are $LnBa_2Cu_3O_{7-\delta}$ (where Ln is a rare-earth element other than Pr, Ce, and Tb) with $T_c \geq 90$ K, and $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ with T_c ca. 20 K for $n = 1$, ca. 80 K for $n = 2$, and ca. 110 K for $n = 3$. Deposition of $LnBa_2Cu_3O_{7-\delta}$ thin films is well established by different deposition techniques, while that of the $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ system for $n = 2$ and 3 is being investigated. Thin film deposition of $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$ ($n = 1, 2, 3$) is limited because of the toxicity of Tl. A more recent development is thin film deposition of $HgBa_2CaCu_2O_{6+\delta}$ by reactive r.f. magnetron sputtering, followed by oxygenation annealing. The film shows a relatively sharp transition up to ca. 120 K [162].

Typical methods for in situ deposition of high-T_c cuprate thin films are physical deposition, e.g., r.f. sputtering, pulsed excimer laser

ablation or pulsed laser deposition (PLD), and reactive coevaporation, sometimes referred to as molecular beam epitaxy (MBE). Radiofrequency magnetron sputtering was first used for deposition or epitaxial growth of $YBa_2Cu_3O_{7-\delta}$ thin films on MgO and $SrTiO_3$ substrates; PLD with ArF ($\lambda = 193$ nm) and KrF ($\lambda = 248$ nm) excimer lasers is a promising method for $LnBa_2Cu_3O_{7-\delta}$ thin films with $T_c > 90$ K [163]. It can now produce in situ deposited multilayered films with different targets installed in a deposition chamber. Figure 36 shows a typical transmission electron micrograph of a $YBa_2Cu_3O_{7-\delta}/PrGaO_3/YBa_2Cu_3O_{7-\delta}/PrGaO_3$ quadrilayered film grown in situ on a $SrTiO_3$ substrate. The great advantage of MBE is its ability to control deposition sequences by observing oscillations of the reflection high-energy electron diffraction (RHEED) intensity [164], which enables "layer-by-layer" deposition of constituents and fabrication of superlattices, e.g., $PrBa_2Cu_3O_x/YBa_2Cu_3O_x$.

Figure 36. Transmission electron micrograph of a $YBa_2Cu_3O_{7-\delta}/PrGaO_3/YBa_2Cu_3O_{7-\delta}/PrGaO_3$ quadrilayered structure on a $SrTiO_3$ substrate deposited in situ by pulsed laser deposition

Most $YBa_2Cu_3O_{7-\delta}$ films grown by physical deposition contain spiral growth islands [165] originating from screw dislocations caused by relatively high supersaturation (Fig. 37). Surface roughness is of the order of 0.01 µm.

Physical depositions require low supersaturation of cuprate-generating species, oxygen pressure control, and choice of epitaxial substrate materials. For supersaturation, the most advanced techniques are metallorganic chemical vapor deposition (MOCVD) for Bi systems, and liquid-phase epitaxy (LPE) for $LnBa_2Cu_3O_{7-\delta}$ systems. Current MOCVD research has obtained high-quality *c*-axis-oriented $YBa_2Cu_3O_{7-\delta}$ thin films with T_c of ca. 90 K and $Bi_2Sr_2CaCu_2O_6$ ($n = 1$, 2212 phase) thin films with a T_c ca. 80 K.

Figure 37. Spiral growth islands of *c*-axis-oriented $YBa_2Cu_3O_{7-\delta}$ thin film revealed by atomic force microscopy
Terraces with step height ca. 12×10^{-10} m.

Liquid-phase epitaxy is the most advanced technology for $LnBa_2Cu_3O_{7-\delta}$ films [166]. The complex phase diagram of $LnBa_2Cu_3O_x$ gives a relatively high epigrowth temperature, 900–970 °C, and as-grown films do not show a superconducting transition, owing to oxygen deficiency; post-growth annealing in oxygen is necessary. Growth is conducted at minimal supersaturation.

Deposition of $LnBa_2Cu_3O_{7-\delta}$ thin films, specifically $YBa_2Cu_3O_{7-\delta}$, has been thoroughly investigated for different deposition techniques. To obtain superconducting $YBa_2Cu_3O_{7-\delta}$ thin films in an as-deposited state, the relationship between oxygen partial pressure during deposition and substrate temperature has been established for different physical deposition techniques (Fig. 38). Oxygen partial pressure during deposition has to be kept close to the critical oxygen pressure at the decomposition of bulk $YBa_2Cu_3O_6$ (nonsuperconducting tetragonal phase). Activation processes to enhance oxidization involve ozone, oxygen plasma, and atomic oxygen radicals. Electron beam deposition involves post-deposition annealing in oxygen.

For epitaxial thin films of $LnBa_2Cu_3O_{7-\delta}$, the choice of substrate materials becomes more important, especially for active device applica-

Figure 39. Lattice constants and thermal expansivities of new substrate materials
Data from $YBa_2Cu_3O_{7-\delta}$ for comparison [168].

tions. Figure 39 [168] shows thermal expansivities of different substrate materials. $LaAlO_3$ seems practical for microwave applications because of its relatively low dielectric constant [169], while $NdGaO_3$ is suitable for *c*-axis-oriented epitaxial thin films because of its good lattice matching [170].

Of current interest is the growth of *a*-axis-oriented $YBa_2Cu_3O_x$ thin films, because of the anisotropy in coherent length ($\xi_{a/b} = 30-40\times10^{-10}$ m and $\xi_c = 5-10\times10^{-10}$ m). This takes advantage of a Josephson coupling junction across an *a*-axis SIS (superconductor – insulator – superconductor) structure. Many workers have reported *a*-axis-oriented $YBa_2Cu_3O_{7-\delta}$ film growth in which the deposition temperature is lowered by ca. 100 °C from the usual *c*-axis film deposition temperature. However, this gives *a*-axis films with 90° domains, T_c ca. 20 K. Meanwhile, *c*-axis in-plane-aligned, *a*-axis-oriented $YBa_2Cu_3O_x$ thin films have been grown on (100)-oriented tetragonal $SrLaGaO_4$ and Nd_2CuO_4 substrates with a K_2NiF_4-type crystal structure. A growth model called "atomic graphoepitaxy" has been proposed [171], where the atomic geometry of a (100)-oriented face of tetragonal K_2NiF_4-type materials is considered. Films grow epitaxially with perfectly in-plane-aligned *c*- and *b*-axes, along both of which $T_c = 90$ K.

When $YBa_2Cu_3O_x$ films are deposited on semiconducting Si substrates, Si ions diffuse easily into the films, and T_c degrades to ca. 70 K or less. As a result, a variety of oxide materials are being investigated as a buffer layer between the film and Si substrate in order to suppress interdiffusion. One such buffer material is yttrium-stabilized ZrO_2 (YSZ).

2.6. Polymer Films

2.6.1. Langmuir – Blodgett Layers of Polymer Films as Materials

The Langmuir – Blodgett (LB) technique (see Section 1.6) is a powerful method for the preparation of ultrathin organic films of defined thickness and molecularly controlled internal structure. It consists of the following essential steps:

1) Spreading molecules on a water surface
2) Compressing them to create a two-dimensional condensed layer
3) Transfer of the layer onto a solid substrate to yield mono- or multilayers

The thickness of the films can be varied, in multiples of the monolayer thickness, between a few nanometers (one monolayer) to a few micrometers (several thousand layers). Polymeric LB layers [172] can be obtained by: in situ polymerization of multilayers of amphiphilic monomers (Fig. 40 A); spreading and transfer of preformed amphiphilic polymers (Fig. 40 B); spreading and transfer of hairy rod polymers (Fig. 40 C).

Figure 40. Architecture of polymeric LB layers
A) Layers prepared from solid-state polymerization of amphiphilic monomers (the polymerization can be carried out either within the monolayer prior to transfer, or within the multilayer assembly); B) Layers prepared from preformed polymers; C) Layers composed of rod-like main chains

Individual layers of amphiphilic monomers or polymers are generally composed of two-dimensional crystallites (Fig. 41). The intercrystallite grain boundaries contribute significantly to the properties of LB films. This can result in losses by scattering in such applications as waveguides or cladding layers, and can play a major role in defining transport properties, e.g., in diffusion barriers or electrical insulators.

Figure 41. Domain structure in multilayer systems

In multilayers of rod-like macromolecules with flexible side chains (hairy rods), the polymer backbones are oriented parallel to one another and are maintained at a fixed separation by the side chains, which form a continuous matrix (Fig. 42). LB layers of hairy rod polymers exhibit good mechanical stability and high optical transparency, and may be considered as molecular composites. The stability of hairy rod polymer films can be increased by cross-linking functional groups attached to the side chains [173].

Characterization Methods (Table 12) [174–176].

Film Thickness. If the thickness of an individual monolayer is known, counting the number of deposition cycles is the simplest method to as-

Table 12. Techniques for the investigation of LB films

	Radiation used	Contrast by	Typical information
Optical interference microscopy	light	optical phase shift	optical thickness, topography of surface
Ellipsometry	light	refractive index difference	optical thickness
Surface plasmon resonance spectroscopy	light	optical phase shift	optical thickness (metric thickness)
X-ray reflectometry	X-rays	electron density difference	electron density profile along layer normal, metric thickness, roughness
Neutron reflectometry	neutrons	selective deuteration	scattering length profile along layer normal, metric thickness, roughness
Contact angle		surface tension	wetting behavior
Adhesion test			adhesion forces
Infrared (IR)/Raman spectroscopies	light	IR/Raman absorption	functional group composition and orientation
Transmission electron microscopy (TEM)	electrons	electron density difference in plane	crystal structure, domain structure and texture
Low-energy electron diffraction (LEED)	electrons	electron density difference	crystal structure of surface layers
Atomic force microscopy (AFM)		height profile or surface tribology	surface topography
Scanning tunneling microscopy (STM)	charge carriers	conductivity differences	chemical composition periodicity of groups
X-ray photoelectron spectroscopy (XPS)	X-rays		elemental surface composition

sess the thickness of the film. The thickness can be determined by a number of experimental techniques. Optical interference techniques yield the "optical thickness," defined as the product of the metric thickness d and the refractive index n; knowledge of the refractive index enables evaluation of the metric thickness. The birefringent character of most LB films is a complicating factor.

Phase-shift interferometry [177] provides a three-dimensional profile of the film. Study of the profile edge enables the film thickness to be determined. This technique requires that a thin metal film be evaporated on top of the LB layers in order to obtain a reflecting surface. The thickness profile can also be determined by mechanical contact methods and, in the case of only a few layers, by atomic force microscopy (AFM).

In ellipsometry, the change in polarization of light reflected from a thin film on top of a metal surface is analyzed to yield accurate information on the optical thickness. Ellipsometry is also a sensitive technique for detecting minor changes during the lateral organization of LB films on the subphase, and has been used to investigate the properties of monomolecular films of fatty acids on both water and mercury subphases.

Surface plasmon spectroscopy [178] is a further method for optical thickness analysis. Surface plasmons are electromagnetic surface waves propagating from a thin metal film into a dielectric medium. Plasma oscillations in the metal film are excited by polarized light from a laser, which couples into the film at a particular angle. The resonance condition for a given system depends on the refractive index and the film thickness. When the LB film is thick enough to be used as a waveguide, the surface plasmon and waveguide modes can be detected simultaneously. Analysis of the waveguide modes gives exact values of the film refractive index and thickness.

The most detailed and accurate information on the thickness of multilayer systems comes from grazing incidence X-ray or neutron reflectometry. The absolute layer thickness can be derived from analysis of the characteristic interference patterns (Kiessig fringes). The thickness of the individual monolayers and the surface roughness of the film can also be obtained.

Surface Properties [174]. Contact angle measurements of various liquids placed on the LB layer can be used to determine surface energy and wetting properties. The adhesion of the first monolayer to the underlying substrate, and of subsequent monolayers to each other, can be determined only qualitatively. A standard adhesive tape is applied to the surface of the film and then detached. Comparison of the film before and after this procedure gives a measure of the amount of film removed.

Grazing incidence infrared (IR) reflection by mono- and multilayers on a metal substrate and polarized IR transmission are powerful tools for

Table 13. Properties and applications of LB films

	Properties	LB films	Applications
Mechanical properties	stability	low	
Optical properties	birefringence	often observed	optical filters
	nonlinear optics (χ^2/χ^3)	observed in films of special composition	optical switches, frequency doubling
Electrical properties	conductivity	up to 10^{-2} – 10 S/cm of special components	interconnection in microelectronic circuits
	resistance	good insulating behavior, low electric loss, e.g., in arachidic acid	capacitors
	photoconductivity	up to 1 % quantum efficiency in special cases	
	electroluminescence	blue light emitted from devices based on aromatics	displays
	pyroelectricity	observed in noncentrosymmetric structures	infrared TV cameras
	piezoelectricity	observed in noncentrosymmetric structures	
Surface properties	lubrication	drastic reduction of static friction by a few monolayers of fatty acids	magnetic storage
	wettability	polarity can be tailored	surface modification of substrates
	surface anisotropy	order parameter high, monodomain structure possible	liquid crystal alignment in displays
	biocompatibility	possible tailoring of surface	artificial implants, sensors
Miscellaneous	permeability	selective permeability often observed	membranes for gas separation, reversed osmosis, ultrafiltration
	chemical reactivity	composition dependent	microlithography, positive and negative resists

the investigation of the orientation of molecular moieties in the LB film. These techniques are sensitive enough to investigate individual monolayers [177].

Raman spectroscopy gives similar information about the structure, orientation, and conformation of the components of thin organic layers. Because of the weak signals, an enhancement mechanism is usually required for the direct observation of LB films. A dramatically increased signal can be produced by waveguide Raman spectroscopy (WRS) and surface plasmon enhanced Raman spectroscopy.

Transmission electron microscopy (TEM) as well as low-energy electron diffraction (LEED) have been used to investigate LB layers. Under optimum conditions single polymer molecules can be observed.

Various scanning near-field microscopies (AFM, STM, SEM, etc.) have been used to gain insight into the surface properties of mono- and multilayer systems.

In X-ray photoelectron spectroscopy (XPS) or electron spectroscopy for chemical analysis (ESCA), the surface is exposed to monochromatic X-rays and the energy distribution of electrons emitted gives information on the chemical composition, environment, and binding of atoms at the surface.

Elastic constants of LB assemblies can be determined by Brillouin spectroscopy [179] or by a quartz crystal resonator [180].

Properties of LB Multilayers and Applications (Table 13) [174, 175, 181]. Polymeric LB films are much more stable than layers composed of monomers, owing to covalent bonding in the film plane. However, the fragility of these systems remains a problem in many applications. The mechanical properties of mono- and multilayers are generally anisotropic, and may be strongly influenced by structural defects.

Optical and Optoelectronic Properties [182, 183]. Birefringence and dichroism are frequently observed in LB layers. Thus, optical filters and devices for optical applications can be prepared. Optical anisotropy can be induced through the introduction of mesogenic side groups. The optical properties of the film may be varied by thermal treatment or the application of an external electrical field. LB assemblies may be used as waveguides; the best attenuation of guided light reported has been ca. 2 dB/cm.

Nonlinear optical effects have received particular attention. To produce χ^2 effects (frequency doubling, electrooptical switching, etc.) noncentrosymmetric LB films of hemicyanines,

phenylhydrazones, or similar polarizable dyes are necessary. Values of the χ^2 parameter ca. 10 – 100 times the value of the commonly used material $LiNbO_3$ have been reported. For χ^3 effects (frequency tripling, phase conjugation, etc.) highly polarizable conjugated π-electron systems with donor – acceptor moieties can be used.

As discussed previously (Fig. 41), the presence of cracks and crystalline domains of sizes in the range of the optical wavelengths must be avoided, and the thermal stability must be enhanced, in order to produce LB films of suitable optic and stability.

Electric and Dielectric Properties [184]. Electrical measurements on LB layers frequently prove difficult, owing to the inherently fragile nature of the specimens. Various effects have been reported which depend on the chemical nature of the constituents and the state of order of the LB assemblies. For example, tunneling barriers have been studied where an LB film was sandwiched between two metal electrodes. LB layers composed of "organic metals" or semiconducting materials have also been reported. The behavior of LB films as conductors and insulators can be optimized by tailoring the molecular components of the film.

Ultrathin organic films between metal contacts have an enormous charge storage capability, which suggests an application as the dielectric layer in simple capacitors.

LB films on semiconductors can be used for various applications, including metal – insulator – semiconductor diodes, Schottky barriers, or field effect transistors. The properties of LB layers in terms of photoelectric transport and as the active layer in electroluminescent devices have been investigated.

Pyroelectricity and piezoelectricity are observed in noncentrosymmetric LB multilayer systems. Owing to the small heat capacity of the film, the pyroelectric response is very fast. Pyroelectric detector systems for thermal radiation based on LB films could be used in fast infrared TV cameras.

Surface Properties [181]. The presence of a single monolayer on any substrate can drastically reduce static friction. This effect can be used to reduce frictional forces between different surfaces in mechanical contact. For example, magnetic mass storage media require very thin, but very stable lubricant layers to avoid wear during transit of the tape across the magnetic head. Good results have been achieved with a few layers of fatty acids on the tape, which also serve as an encapsulant to protect the magnetic media.

The wettability of a specific surface can be profoundly influenced by coverage with only one or a few monolayers, e.g., turning a hydrophobic surface into a hydrophilic one. This offers the possiblity of tailoring the surface properties of different substrates. In the field of liquid crystal displays, orientation layers are commonly used to align liquid crystals parallel to the surface. LB films with uniaxial or biaxial orientation, prepared by carefully controlled deposition procedures, are contenders for liquid crystal alignment layers. Excellent results have been reported for ω-tricosenic acid films, polymerized by an electron beam. With azobenzol-dye-containing monolayers, a change of orientation of the liquid crystals from parallel to homeotropic can be induced by photoinduced *cis – trans* isomerization.

The LB technique allows control of surface charge densities, surface potential, degree of hydrophobicity, and type and concentration of functional groups on the surface. It has therefore been proposed to use this to produce coatings on medical devices and, in particular, on implants. To date, only model systems have been developed.

Permeability [174]. The architecture of LB multilayers of amphiphilic compounds in many ways mimics biological membranes, suggesting possible applications in specific separation tasks, such as ultrafiltration, reverse osmosis, and gas separation. In these situations LB films with high selectivity are deposited on a porous, mechanically stable support. For example, eighteen monolayers of hexacosa-10, 12-diyonic acid on a porous polypropylene support reduce the gas flow of methane by a factor of 30 compared with the uncoated substrate. Structural defects in LB films deposited directly onto the porous support often generate leakage problems. These can be resolved by a composite technique. A very thin, nonporous, but highly permeable layer is installed between the LB film and the porous membrane, which dramatically reduces the number of defects in the film.

Chemical Variation of LB Multilayers [185]. The polymerization of an LB layer composed of amphiphilic monomers can be initiated locally by UV or high-energy radiation. Resist structures may thus be prepared with a resolution better than 100 nm. This is of importance for integrated circuit technology, where submicrometer resolution lithography is a crucial element of process technology. Both positive and negative resists have been successfully used; simple fatty acid salts show high resolution as positive resists, subliming under irradiation. Enhanced sensitivities are more easily achieved with negative resists, in which case polymerization is initiated by an electron beam. Several types of polymerizable materials have been investigated. The topochemical polymerization of diacetylenic amphiphiles and of ω-tricosenoic acid show promising results. Transfer of these ultrafine structures to solid substrates, however, requires improvement of the resistance of the LB film to plasma etching. Polysiloxanes and polysilanes are good candidates for this task.

LB Films as Sensors (Table 14) [175]. The properties of LB films as described above suggest many possible applications to sensory devices. The extremely high ratio of surface area to bulk volume of LB films prevents bulk diffusion, and yields fast response and recovery times. The ordered surface allows a maximum of reactive species per unit surface area, and offers the potential of high selectivities via appropriate molecular design. In particular, exploitation of the intrinsic selectivity of biological systems (e.g., enzyme – substrate, antibody – antigen, and receptor – transmitter) can be incorporated into the design.

Table 14. LB films as sensors

	Sensitive absorbing LB layer on top of	Physical parameter changes by absorption of analyte
Field-effect transistor devices	semiconductor	dielectric properties
Optical sensors	optical waveguide	optical spectrum
Surface plasmon resonance devices	sandwiched between metal surface and prism	refractive index, film thickness
Ellipsometric sensors	metal surface	refractive index, film thickness
Acoustoelectric sensors	oscillating quartz	mass of film

A wide range of sensors based upon LB films have been investigated. Chemically sensitive field-effect transistor (ChemFET) sensors detect chemical changes in a medium which is in contact with a metal oxide – semiconductor FET. Changes in this medium cause an alternation in the surface potential within an LB layer placed on top of the FET device. Profound effects on the measurable parameters of a device are noted with even minute changes in the dielectric properties of the interfacial region.

Changes in surface conductivity induced by the interaction of specific gases with semiconducting LB films have formed the basis for the construction of gas sensors.

Optical sensors detect changes in the optical spectrum of an LB film resulting from the adsorption of an analyte. As an example, the fluorescence of porphyrin LB layers can be quantitatively quenched through the absorption of gases such as NO_2 and HCl. Other optical methods include plasmon resonance or ellipsometric detection of changes in the refractive index or surface thickness when a substrate interacts with the surface layer.

Acoustoelectric sensors are based on the principle that the resonant frequency of a vibrating body is altered when the surface coverage is changed. Thus, the resonance frequency of a piezoelectric quartz crystal coated with LB layers of ω-tricosenoic acid is changed on adsorption of hydrogen sulfide.

2.6.2. Films by Plasma Polymerization

Films formed by plasma polymerization differ from normal polymer material in several respects. A wide range of structure can be fabricated by modifying the plasma conditions (pressure, flow rate, and power). A map delineating different material regions may be constructed using these parameters. In ethylene, for example, it is possible to produce soft and hard films, powder and oil, as well as mixtures of these [186]. It is believed that powder is formed when the reaction occurs primarily in the gas phase, and is facilitated by long residence times, high power, and reactive monomers. Both IR and NMR have been used to investigate polymer film structure. Models of the structure of the oil and film products from plasma-polymerized

Figure 43. Plasma-polymerized material from ethylene monomer [187]
A) Oil model; B) Film model

ethylene are shown in Figure 43 [187]. A second feature of plasma polymerization is that almost any monomer can be used: organic, organometallic, or containing silicon. The monomer need not contain unsaturated groups. In plasma-polymerized material, very few monomer units remain in a regular repeating pattern as in conventional polymerization. The morphology of plasma films has been investigated by X-ray scattering und electron microscopy (e.g., powder particles in plasma-polymerized ethylene on a chromium substrate observed by transmission electron microscopy [186]).

Plasma films contain significant quantities of long-lived free radicals. In plasma-polymerized styrene, one in twenty polymer molecules is a radical site. The radicals are formed either directly in the energetic plasma, and then incorporated in the growing film, or by reactive plasma species or plasma radiation impinging on surfaces. Because the polymer molecules are strongly cross-linked (Fig. 43), the radicals are immobile and long lived. They are shorter lived if the film is exposed to the atmosphere, when they react with water vapor or O_2 (appearance of the characteristic IR bands of OH and CO in exposed film). If a high free radical density is undesirable, it can be reduced by heating or by subsequent exposure to a hydrogen plasma.

Another important characteristic of plasma-polymerized film is its impermeability. This is due in part to cross-linking. The mechanism of permeation in these films has been considered by Yasuda [188] who classified plasma films as intermediate between two ideal cases: solution – diffusion or molecular sieve mechanisms. Plasma films often show extremely low permeability to water, e.g., a methane polymerized film is two orders of magnitude less permeable than conventional polymeric material [188].

An important feature of polymerized plasma films is the presence of compressive intrinsic stress, the molecular origin of which is believed to be the high nonequilibrium density of the films due to their highly cross-linked structure. Intrinsic stress has been widely studied because of its implications for film stability. Methods of alleviating it include annealing at 100 – 300 °C. Intrinsic stress is not observed for all polymer films, and films formed from closely related monomers often exhibit quite different stress characteristics. Internal stress is generally larger under slower deposition conditions and increases with film thickness, eventually leading to cracking. Better barrier and adhesion properties are to be found in thinner films. The amount of stress also depends on the substrate and its thermal properties relative to the plasma film deposited on it [188].

The electrical properties of plasma films have received much attention. Initially it was believed that they had great potential for forming thin dielectric coatings, but there are some serious drawbacks. Their dielectric properties are susceptible to aging, primarily due to the reactive nature of the film when exposed to air. This behavior is often irreproducible from one film to another, even from the same batch. A second problem is high dielectric loss. Both features are believed to originate from the free radicals in the films, and attempts have been made to eliminate them by heat treatment in vacuo. The effects of O_2 and humidity on conduction properties have also been recognised. The effect of O_2 on plasma polymer from styrene monomer is an irreversible decrease in conductivity by three orders of magnitude. Photoconduction and bistability have also been investigated.

Potential applications of plasma films which seek to exploit their special properties have been reported [189]. The synthesis of osmotic membranes from plasma polymer deposited on porous substrate has produced materials which can efficiently separate salt solutions. Salt rejection as high as 98 % has been repeated with nitrogen-containing polymers at fluxes of $320\,\mathrm{L\,m^{-2}\,d^{-1}}$. Permselective membranes for separating gas mixtures have been applied to H_2/CH_4, H_2/CO_2, and He/CO_2 mixtures.

The adhesion properties of the films on a number of substrates and their pinhole-free, cross-linked structure have led to their use as barrier coatings. They have been used to protect metals and moisture-sensitive optical components such as alkali halide crystals. For the latter, fluorinated ethylene films have been used which also give the coated components antireflection properties, which can be varied by changing the monomer and its thickness. Abrasion-resistant coatings can be made from hard films and several silicon-containing monomers have been used.

2.7. Optical Coatings

2.7.1. Introduction

The characteristic colors of most substances have their origin in selective molecular absorption (chemical colors). Other colors are a result of physical structure. These physical colors have the advantage over chemical colors that they do not fade.

Some physical colors found in nature are iridescent, interference colors, e.g., peacock feathers. “Interference colors are the purest and most brilliant colors known to man. They cannot be

matched by even the brightest pigment colors in depth and intensity" [190].

Optical coatings are artificial thin films. Although they can be used to color objects, they are normally deposited on optical elements to modify spectral reflection and transmission. Their uses range from the UV to the far IR. The number of individual films can be up to several hundred. Since each additional thin film adds another interface (the origin of an additional partial reflection, contributing to the interference) very high reflections, very low reflections, and steep transitions can be accomplished.

2.7.2. Theory

The primary elements of thin film interference are the reflections and the spacings of the interfaces. For nonabsorbing films, this can be related to the indices of refraction n and the optical thicknesses nd of the individual films. The reflectance R of a nonabsorbing optical coating consisting of m individual layers is given by

$$R = 1 - \frac{4n_0 n_s}{2 + (n_0/n_s)\, M_{11}^2 + n_0 n_s M_{12}^2 + M_{21}^2/n_0 n_s + (n_s/n_0)\, M_{22}^2}$$

where n_0 is the refractive index of the surrounding medium (air), n_s that of the substrate, and M_{11}, M_{12}, M_{21}, M_{22} are the elements of the characteristic matrix of the multilayer:

$$M = \begin{bmatrix} M_{11} & iM_{12} \\ iM_{21} & M_{22} \end{bmatrix} = \prod_{\nu=1}^{m} \begin{bmatrix} \cos\Phi_\nu & \frac{i\sin\Phi_\nu}{n_\nu} \\ in_\nu \sin\Phi_\nu & \cos\Phi_\nu \end{bmatrix}$$

where n_v is the refractive index, $\Phi_\nu = \frac{2\pi}{\lambda} n_\nu d_\nu \cos\alpha_\nu$ the phase thickness, λ the wavelength, d_ν the physical thickness of the νth layer, and α_ν the angle of incidence at the $(\nu+1)$th interface.

The "design" process of fitting the spectral reflectance of a multilayer to a prescribed spectral curve generally follows one of two methods:

1) The designer is in charge and the computer is used merely as a calculator (split-filter synthesis [191], equivalent layers [192], and Chebyshev prototypes [193]).
2) The computer is in charge and the decisions of the designer are reduced to a minimum (refinement [194] and computer synthesis: comprehensive search [195], flip-flop [196], and inverse Fourier transforms [197]). Several excellent programs are commercially available [198].

2.7.3. Deposition Methods

Four deposition methods are used commercially:

1) High-vacuum evaporation from boats or with electron guns [199]
2) Dipping [200]
3) Energetic deposition processes [201] (d.c. magnetron sputtering, ion plating, and ion-assisted evaporation)
4) Chemical vapor deposition (low-pressure CVD [202], plasma-enhanced CVD [203], and plasma-impulse CVD [204])

Figure 44 estimates the share and trend of each of these methods in world manufacture of optical coatings (total market \$ 1.1×10^9 in 1992 [205]).

Figure 44. Past and projected market share of deposition methods for optical coatings
a) Evaporation/dipping; b) Sputtering/ion plating/ion-assisted evaporation; c) Plasma CVD, PICVD/PECVD

2.7.4. Coating Materials

Table 15 lists typical coating materials. Mixed oxides are also feasible, but the proportions must allow congruent evaporation, with energetic deposition processes, silicon and aluminum nitrides are also possible.

Table 15. Refractive indices and ranges of transparency for typical coating materials [206]

Material	Wavelength, µm					Range of transparency, µm
	0.35	0.55	1	1 – 8	10	
Ge				4.20	4.20	1.7 – 25
Si			3.90	3.42		1 – 9
TiO_2		2.32	2.20			0.4 – 6
ZnS		2.36	2.27			0.4 – 14
ZrO_2	2.15	2.05	2.00			0.3
Ta_2O_5	2.31	2.16	2.09			0.3
SiO		2.00	1.90	1.85		0.5 – 8
Al_2O_3	1.66	1.63	1.60			0.15 – 9
Si_2O_3		1.57	1.55			0.3 – 8
SiO_2	1.48	1.46	1.45			0.16 – 8
MgF_2	1.39	1.38		1.36		0.13 – 10
Cryolite			1.30 – 1.35			0.13 – 9

The quality of optical coatings depends on the preparation of the coating materials. Most materials come in 1 – 2 mm granules and are vacuum sintered. Often, small additions of foreign material reduce crystallization and increase homogeneity.

2.7.5. Classical Coatings

The characteristics of Figure 45 can be generated from the UV (0.2 µm) to the IR (50 µm) range of the spectrum. Since different coating materials are necessary in different spectral regions (Table 15), the quality of match to the ideal curve depends on wavelength.

In the visible (0.4 – 0.7 µm) the following performance figures are possible:

1) Reflectances as low as 0.01 % for narrow regions and < 0.3 % over the whole visible spectrum
2) Reflectances as high as 99.99 % for narrow regions and 99.8 % over the whole visible spectrum
3) Transition from low (< 5 %) to high reflectance (> 95 %) within an interval $< 0.01\ \lambda$
4) Narrow bandpass filters with bandwith as small as 10^{-10} m
5) Minus filters with bandwidth ca. $0.01\ \lambda$

Figure 45. Characteristics of classical optical interference coatings

2.7.6. Nonclassical Coatings

Of increasing importance are optical coatings which, in addition to being part of the interference system, serve an electrical or magnetic function:

1) Transparent conductive coatings: indium–tin oxide conducts electricity well, but is optically transparent [207]. Surface resistance of a few Ω/m^2 at 90 % transmittance can be accomplished.
2) Electrochromic coatings: colorless amorphous WO_3, on injection of electrons and charge-compensating positive ions, transforms to blue hydrogen tungsten bronze [208].
3) Electroluminescent coatings: Mn-doped ZnS films, deposited at ca. 225 °C, emitlight in an electrical field [209].
4) Magneto-optical films: sputtered alloys of Tb, Fe, and Co show a large Kerr rotation, and can be used for high-efficiency magneto-optical recording [210].
5) Diamond-like films: under certain conditions, carbon films can assume a diamond or diamond-like structure [211].

2.7.7. Applications

Optical coatings have the following four effects:

1) Improved performance of optical components
2) Adaptability to most needs
3) Protection (often harder than the substrate)
4) Solution of otherwise intractable problems

They play key roles in the following areas:

1) Displays: cathode ray tube contrast enhancement, r.f. interference shielding, transparent electrodes for liquid crystal displays, liquid crystal light valves for high-definition television, head-up displays, shop window antireflection coatings
2) Photography/video: antireflection coatings for lenses, mirrors, filters, color film processors, enlarging heads, professional and amateur television cameras
3) Eyeglasses: antireflection coatings, sunglasses, photochromic glasses, high-efficiency sunglasses, frames, laser goggles, welding goggles, electrochromic glasses
4) Lighting: regenerative lamps; low-height, wide-angle street lamps; shopping display lights; traffic/railroad lights; movie projectors; disco lights; stage lighting; dental/surgical lighting
5) Instruments/lasers: antireflection coatings, beam dividers, mirrors, filters, variable filters, Raman spectroscopy filters, fluorescence microscopy filters, laser end mirrors, laser windows, high-power polarizers, laser gyro coatings
6) Photocopiers/data storage: high reflectors for photocopiers, compact disk players, optical data disks, magneto-optical data disks, optical read/write heads
7) Security: burglar alarms; anticounterfeiting for documents, licenses, and currency
8) Buildings: summer films, winter films, antireflection coatings, "smart" windows
9) Automobiles: rear-view mirrors, scratch-resistant coatings for plastic windows, heat-reflecting windows, plastic headlights
10) Optical communications: antireflection coatings on laser ends, narrow-band filters, wavelength-division multiplexers
11) Integrated optics: waveguide coatings, antireflection coatings, integrated filters
12) Home appliances: oven windows, oven wall heater reflectors, optical pot heaters
13) Applied art: jewelry, iridescent color effects, optical art
14) Flexible substrates: architectural window films, cathode ray tube contrast enhancement films, touchscreens, inexpensive solar reflectors, iridescent packaging, interference ink, lightweight mirrors, optically enhanced packaging

2.8. Membranes [212–214] (→ Membranes and Membrane Separation Processes)

2.8.1. Introduction

Membranes consist of thin solid or liquid films that act as barriers for the transport of molecular components. Synthetic membranes are widely used in applications such as water desalination

and gas separation or the concentration and purification of food and chemical products, and notably in medical devices, such as artificial kidneys or drug delivery systems. In energy conversion and storage systems, e.g., batteries, fuel cells, and electrolyzers, membranes also play an important role.

2.8.2. Fundamentals

Membranes used in various applications differ in their functions, structures, and materials. In general terms, a membrane is defined as a solid or liquid, homogeneous or heterogeneous barrier that separates two phases and restricts the transport of different components from one phase to the other in a specific way. To separate molecular mixtures, membranes must have different permeabilities for different components. For high mass transport rates per unit area, membranes should be as thin as possible; they are usually thin films or hollow fibers. To obtain a transport through a membrane, driving forces are required, i.e., differences in the electrochemical potentials of the various components such as differences in concentration, hydrostatic pressure, or electrical potential between the two phases separated by the membrane. Transport of a component is determined by its concentration and mobility in the membrane. Mobility is determined by the hydrodynamic resistance in pressure-driven processes, and by diffusivity of the component in the membrane matrix in concentration gradient- or electrical potential-driven processes. Concentration in the membrane is determined by solubility in homogeneous membranes, by exclusion due to size in porous membranes, or due to electrical charge in ionexchange membranes. Concentration and mobility of certain components in a membrane may be facilitated by functional groups incorporated in the membrane matrix (facilitated transport).

2.8.3. Membrane Structures and their Preparation

Classification. Although synthetic membranes vary widely in structure, function, and material, they can be classified into typical groups (Table 16). This classification is rather arbitrary and many structures used today may fit none or more than one of these classes.

Table 16. Synthetic membranes

Structure	Material	Function
Porous films, hollow fibers	polymers, ceramics, metals	gas separation micro- and ultrafiltration, dialysis
Homogeneous films, hollow fibers	polymers, metals	reverse osmosis, gas separation, pervaporation
Homogeneous or porous films with fixed ions	polymers, ceramics	electrolysis, electrodialysis, dialysis
Asymmetric porous or homogeneous films	polymers, ceramics	pressure-driven membrane processes
Thin film composite membranes	polymers, ceramics	pressure-driven membrane processes
Liquid films with selective carriers	organic liquids	selective removal of ions, gases, etc.

Preparation. The techniques used for manufacturing the various membrane structures are very different. For the preparation of microporous membranes from ceramics or polymers, pressing and sintering of a fine powder is used. Irradiation of a thin film followed by acid or alkaline etching or the precipitation of polymer from a solution by a non-solvent are also used to prepare porous membranes. Homogeneous membranes are prepared by extrusion of a metal or a polymer into a thin film or by casting polymer solution as a thin film and evaporating the solvent. Asymmetric structures are generally made by phase inversion techniques and composite membranes by dip-coating or interfacial polymerization. Techniques for making liquid membranes include the formation of emulsions for the preparation of unsupported liquid membranes and the filling of porous structures with liquid for the preparation of supported liquid membranes.

Processes. Membrane separation processes can differ significantly with regard to the membranes, the applied driving forces, the areas of application, and the industrial relevance (Table 17).

Applications. Synthetic membranes are used not only in separation processes, but also in medical devices as barriers for the controlled

Table 17. Technical relevant membrane separation processes

Separation process	Membrane type	Driving force	Application
Microfiltration	symmetric porous membranes	hydrostatic pressure 10 – 500 kPa	sterile filtration, clarification
Ultrafiltration	asymmetric porous membranes	hydrostatic pressure 0.1 – 1 MPa	filtration of macromolecular solutions
Reverse osmosis	asymmetric homogeneous membranes	hydrostatic pressure 2 – 10 MPa	desalination of saline solutions
Dialysis	symmetric porous membranes	concentration gradient	separation of microsolutes from macromolecular mixtures
Electrodialysis	ion-exchange membranes	electrical potential gradient	desalination of ion-containing solutions
Electrolysis	ion-exchange membranes	electrical potential gradient	chlor-alkaline production
Gas and vapor separation	asymmetric homogeneous membranes	vapor pressure gradient	separation of gases and vapors
Pervaporation	asymmetric homogeneous membranes	vapor pressure gradient	separation of azeotropic mixtures

Table 18. Technically relevant applications of synthetic membranes

Separation process	Controlled-release systems	Membrane reactors, immunoisolation	Energy conversion and storage
Microfiltration	therapeutic drug delivery devices	enzyme and catalytic reactors	battery separators fuel cell and electrolyzer separators
Ultrafiltration	artificial organs	biosensors	
Reverse osmosis	sustained-release of pesticides	immunoprotection of cell implants	solid electrolytes
Dialysis			
Electrodialysis			
Gas Separation			
Pervaporation			

release of drugs and in energy-conversion systems as ion-permeable separators (Table 18). For large-scale applications in the chemical and food industry or in environmental protection, separation processes, such as micro- and ultrafiltration or gas separation are most important, but commercially the medical uses of membranes, e.g., in artificial kidneys, are equally interesting.

1. Organic Thiocyanates

1.1. Introduction

Organic thiocyanates are esters of thiocyanic acid. In the general formula R−S−C≡N, the group R can be aliphatic, alicyclic, aromatic, or heterocyclic. So far, no organic thiocyanates have been detected in plants or animals.

Special applications have been discovered and developed for only a few synthetic thiocyanates. Certain organic thiocyanates are used as vulcanization accelerators, others have been used as preservatives because of their biocidal and fungicidal properties. Small quantities are produced as fine chemicals.

1.2. Physical Properties [1]

The low molecular mass alkyl thiocyanates are colorless oils with an odor reminiscent of leeks. They are insoluble in water, but soluble in ethanol and ether, for example. Some physical properties are listed in Table 1.

1.3. Chemical Properties

Thiocyanates isomerize on warming to isothiocyanates. Allylic and tertiary thiocyanates isomerize rapidly, so some thiocyanates can be converted quantitatively to isothiocyanates [2]. In the case of methyl thiocyanate, it is possible to produce methyl isothiocyanate on an industrial scale by isomerization (Section 2.4).

Reducing agents cleave thiocyanates to thiols and hydrogen cyanide.

$$\mathrm{RSCN + [H] \longrightarrow RSH + HCN}$$

The reduction can be carried out with Sn/HCl, $LiAlH_4$, or sodium in liquid ammonia.

Organic thiocyanates are converted to sulfonic acids by strong oxidizing agents:

$$\mathrm{R-SCN + [O] \xrightarrow{H_2O} RSO_3H}$$

The most commonly used oxidizing agent is nitric acid, but alkaline hypochlorite or hydrogen peroxide can also be used. Acid hydrolysis of organic thiocyanates leads to thiols via thiocarbamates:

$$\mathrm{R-SCN \xrightarrow[(H^+)]{H_2O} R-S-C(=O)NH_2 \xrightarrow[(H^+)]{H_2O} RSH + CO_2 + NH_3}$$

Alkaline hydrolysis gives the corresponding disulfides in good yields [3]:

$$\mathrm{2\,RSCN + 2\,OH^- \longrightarrow RSSR + OCN^- + CN^- + H_2O}$$

Because of its polarity, the C≡N bond can undergo addition reactions. Intramolecular reac-

Table 1. Physical properties of some thiocyanates

Name, formula	M_r	CAS	Freezing point, °C	Boiling point, °C (kPa)	Density, g/cm^3
Methyl thiocyanate, CH_3SCN	73.11	[*556-64-9*]	– 51	132 (101.3)	1.074
Ethyl thiocyanate, C_2H_5SCN	87.14	[*542-90-5*]	– 85.5	145.5 (101.9)	1.011
3-Thiocyanatopropyltriethoxysilane, $(C_2H_5O)_3Si(CH_2)_3SCN$	263.42	[*34708-08-2*]	– 80	95 (0.013)	1.000
2-(2-Butoxyethoxy)ethyl thiocyanate, $C_4H_9OC_2H_5OC_2H_5SCN$	205.28	[*112-56-1*]		120 – 122 (0.266)	1.016
Methylenebis(thiocyanate), $NCSCH_2SCN$	130.18	[*6317-18-6*]	103 – 104		

tions for the synthesis of heterocycles are particularly important [4], [5].

1.4. Production

An important method for the production of alkyl thiocyanates is substitution of a halogen in an alkyl halide by the thiocyanate anion. The most frequently used solvents are ethanol, water, and DMF [4], [6]. As the thiocyanate anion is ambidentate, the reaction can give mixtures of thiocyanates and isothiocyanates, or can proceed selectively to either isomer [7]:

The selectivity of the reaction depends on the solvent, temperature, and thiocyanate concentration. Methylenebis(thiocyanate) [8–10] and methyl thiocyanate [11], [12], for example, can be produced by this method.

Organic thiocyanates isomerize partially or completely to the corresponding isothiocyanates during the production process, depending on the type of compound. For example, only isothiocyanates can be produced from β,γ-unsaturated alkyl halides.

Aromatic thiocyanates can be produced by reaction of arenes with dicyanodisulfane. Addition of a Lewis acid increases the electrophilicity of the dicyanodisulfane so much that even unreactive aromatics react:

A further route for the production of aromatic thiocyanates involves reaction of diazonium compounds with salts of thiocyanic acid in the presence of copper salts:

A valuable extension of the possibilities for producing organic thiocyanates is the reaction of thiols with cyanogen chloride [13], particularly as no isomeric isothiocyanate can be formed.

$$RSH + ClCN \longrightarrow RSCN + HCl$$

Other methods exist for the production of organic thiocyanates, but these are not of industrial interest.

Thiocyanic acid adds to epoxides, forming 2-hydroxyalkyl thiocyanates [14], [15]:

Addition of dicyanodisulfane to olefins results in quantitative formation of dithiocyanatoalkanes; the reaction is used to detect double bonds analytically in fat chemistry [16]. Radical initiators or sunlight accelerate the reaction, so a radical addition mechanism is probable.

Reaction of alkylating agents, e.g., dialkyl sulfates or alkyl sulfonates, with salts of thiocyanic acid gives organic thiocyanates [17], [18]:

$$R^1\text{–}SO_2OR^2 + MSCN \longrightarrow R^2SCN + R^1\text{–}SO_2OM$$

An overview of production methods for thiocyanates can be found in reference [6].

1.5. Use and Commercial Names

Industrial applications of organic thiocyanates have been developed for only a few compounds.

Methyl thiocyanate is isomerized to methyl isothiocyanate on an industrial scale (Section 2.4). A small number of compounds are used as insecticides. The compounds known as Lethanes [19] are used as contact insecticides for flies, mosquitoes, and household pests. Lethane 384 [*112-56-1*] has the formula $C_4H_9OC_2H_4OC_2H_4SCN$; Lethane 60 [*301-11-1*] has the formula $C_{11}H_{23}COOC_2H_4SCN$.

Lethane 60 (2-thiocyanatoethyl dodecanoate) is tolerated better by plants than Lethane 384 (2-(2-butoxyethoxy)ethyl thiocyanate) and can thus be used for combatting greenfly.

Methylenebis(thiocyanate) (MBT) and 2-(thiocyanatomethylthio)benzothiazole [*21564-17-0*] [20] exhibit biocidal properties. Both compounds are supplied ready for use in widely differing formulations under the name Busan. The quantities required for use as biocides are predicted to rise [21].

MBT hinders the propagation of slime-forming bacteria and fungi. As Busan 110, it is preferably used in refrigerator circulation systems and in papermills as a 10 % solution in inert solvents [22]. To lower the COD in the circulation water in papermills MTB is used as a stable aqueous dispersion [23]. MTB is employed as a fumigant for counteracting fungal growth [24]. Other applications of methylenebis(thiocyanate) are described in the literature [25–28].

2-(Thiocyanatomethylthio)benzothiazole has been known as a pesticide for a long time [29]. It is sold as a solution in an inert solvent under the name Busan. It is used as a broad-spectrum bactericide und fungicide in various areas. It is thus possible to preserve water-based or organic-solvent-based dyes with Busan 30 [30]. All types of wood are protected from fungi and insects by a coating of the substance. Attack of leather by mold during processing can be prevented by treatment with 2-(thiocyanatomethylthio)benzothiazole [31], [32]. An advantage of the compound over pentachlorophenol is its better environmental compatibility.

3-Thiocyanatopropyltriethoxysilane (Si 264), $(C_2H_5O)_3SiCH_2CH_2SCN$, is used as a reinforcing additive in molding compounds which can be vulcanized by heating with peroxides. The molding compounds are more readily processed, and the polymer obtained after vulcanization has markedly improved properties [33].

1.6. Toxicology

In the case of alkyl thiocyanates, the toxicity in rodents after oral and subcutaneous administration decreases with increasing molecular mass. The higher homologues have an irritant, sometimes corrosive effect on the skin and mucous membranes. They cause irreversible damage to the outer epithelium, death of tissue (necrosis), and defect formation (ulceration), with subsequent hyperplastic reconstruction of the outer epithelium. The systemic toxicity is high (Table 2). Acute poisoning leads to a high degree of circulatory disturbance in the inner organs, with increases in circulation, bleeding, and possibly death.

2. Organic Isothiocyanates

2.1. Introduction

Organic isothiocyanates are esters of isothiocyanic acid. In the general formula R−N=C=S, the group R can be aliphatic, alicyclic, aromatic, acyl, or heterocyclic.

Organic isothiocyanates do not occur naturally in the free form. They are liberated from glucosinolates in plant tissues by enzymatic degradation. Their pungent odor and sharp, mustard-like taste gave these compounds the name mustard oils, by analogy with the ethereal oils of black mustard [34]. Allyl isothiocyanates are liberated from the glucosinolate sinigrin of black mustard by myrosinase [35], [36]. Methyl isothiocyanate is formed by the enzymatic degradation of glucocapparin, which is contained in the caper plant.

Glucocapparin

Table 2. Toxicological data for important organic thiocyanates

Name	RTECS	Administration route	Species	LD_{50}, mg/kg
Methyl thiocyanate	XL 1575000	oral	rat	60
		intravenous	mouse	18
Methylenebis(thiocyanate)	XL 1560000	oral	rat	161
		intravenous	mouse	3.6
2-(2-Butoxyethoxy)ethyl thiocyanate	XK 8400000	oral	rat	90
		intravenous	mouse	56
2-(Thiocyanatomethylthio)benzothiazole	XK 8150000	oral	rat	1590
		dermal	rabbit	642

Many other organic isothiocyanates with, e.g., sulfur-containing or aromatic groups have become known as natural products through the degradation of the corresponding glucosinolates.

Aliphatic and aromatic isothiocyanates are important starting materials for the production of thiourea derivatives, substituted thiosemicarbazides, heterocycles, and other organic intermediates. Some isothiocyanates have nematocidal, bactericidal, and fungicidal properties. Allyl (→ Flavors and Fragrances, Chap. 2.1.6.), methoxycarbonyl, and methyl isothiocyanate are produced on an industrial scale.

2.2. Physical Properties

Most aliphatic and aromatic isothiocyanates are colorless oils with a pungent odor. Methyl isothiocyanate (→ Nematocides) is a solid at room temperature. Many isothiocyanates are not only relatively stable to water in the cold, but can also be steam distilled. Aliphatic isothiocyanates with the general formula R−N=C=S, in which R is an unbranched or branched alkyl group with 2 – 6 carbon atoms, distil azeotropically with water at 80 – 120°C. The boiling points of the pure compounds lie in the range 120 – 200 °C.

Organic isothiocyanates are readily soluble in most common organic solvents.

Table 3 shows the most important physical properties of some isothiocyanates (for further data on isothiocyanates see reference [1]).

2.3. Chemical Properties

The chemical properties of organic isothiocyanates are similar to those of organic isocyanates, but the latter are generally more reactive [37]. Most reactions of isothiocyanates involve addition of a nucleophile to the −N=C=S group. Some examples of nucleophilic addition are given below [1], [38]:

Table 3. Physical data for some isothiocyanates

Name	M_r	CAS	Freezing point, °C	Boiling point, °C (kPa)	Density, g/cm^3
Methyl isothiocyanate, CH_3NCS	73.11	[*556-61-6*]	35.9	118.7 (100.9)	1.0691 (37°C)
Allyl isothiocyanate, $CH_2{=}CHCH_2NCS$	99.15	[*57-06-7*]	−102.5	151.8 (100.7)	1.015 (20°C)
Phenyl isothiocyanate, C_6H_5NCS	135.18	[*103-72-0*]	−21	221 (100.5)	1.138 (15.5°C)
Vinyl isothiocyanate, $CH_2{=}CHNCS$	85.12	[*1520-22-5*]		46 (10.0)	1.018 (15°C)
Methoxycarbonyl isothiocyanate, $CH_3OCONCS$	117.10	[*35266-49-0*]		30 (0.12)	1.152 (15°C)

Isothiocyanates have a very important function in the synthesis of heterocycles. The large number of reactions which have been discovered is notable, and with them access to new compounds has become possible [39–42].

Interest in the development of corresponding synthetic processes was directed towards five- and six-ring heterocycles, but four- and seven-ring systems can also be synthesized, such as benzimidazoles, benzothiazoles, and other bicyclic heterocycles.

Amino acids can be converted to thiohydantoin derivatives [43]:

Acyl isothiocyanates react with 1,3-diketones to 5-acyl-4*H*-1,3-oxazine-4-thiones [44]:

Anthranilic acid reacts with methyl isothiocyanate to 3-*N*-methyl-2-thioxotetrahydroquinoxalin-4-one [45]:

The isothiocyanate group −N=C=S can undergo cycloadditions with suitable reaction partners. Methyl isothiocyanate reacts with sodium azide to 5-mercapto-4-methyl-1,2,3,4-tetrazole [46]:

2.4. Production

A large number of processes are known for the production of isothiocyanates [39], [41], [47], [48]. The structure desired and sometimes the other functional groups on the organic skeleton determine the choice of production process.

The most important production methods are:

1) Reaction of alkyl and acyl halides with salts of thiocyanic acid [49], [50]
2) Isomerization of esters of thiocyanic acid [51], [52]
3) Reaction of dithiocarbamates (→ Dithiocarbamic Acid and Derivatives, Chap. 4.6.) with: hydrogen peroxide [53], [54], cyanogen chloride [55], cyanuric chloride [56], chloroformates [57], alkali hypochlorite or alkali chlorite [58], phosgene [59], heavy metal salts [60], atmospheric oxygen [61], [62], phosphorus oxychloride [63]
4) Reaction of primary amines with thiophosgene [64]
5) Reaction of thiourea derivatives with mineral acids, or acetic anhydride, or by heating [39]
6) Addition of thiocyanic acid to unsaturated compounds [65]

For vinyl isothiocyanates, special production methods are usually necessary [48].

Methyl isothiocyanate, which is industrially important, is produced by two different processes:

1) Rearrangement of methyl thiocyanate

2) Oxidation of sodium *N*-methyldithiocarbamate with hydrogen peroxide

The isomerization of methyl thiocyanate begins above 100 °C. The reaction is catalyzed by salts, e.g., $ZnCl_2$, alkali-metal thiocyanate [2].

$$CH_3SCN \longrightarrow CH_3N{=}C{=}S$$

A patent specification by Morton Chemical [52] describes a multistep continuous process for the isomerization. The temperature of the reaction, which requires a long induction period, is 130 – 160 °C. In the course of reaction, a mixture is formed, which promotes the isomerization autocatalytically and favors the shift in the equilibrium. The methyl isothiocyanate formed is continuously removed from the vapor phase together with methyl thiocyanate. This mixture is subjected to fractional distillation and the methyl thiocyanate is recycled into the isomerization. The methyl isothiocyanate removed is replaced by fresh methyl thiocyanate. The side products formed (sulfides, disulfides) are removed periodically from the liquid phase. It is possible to convert up to 90 % of the methyl thiocyanate into isothiocyanate by this process.

A patent specification by Stauffer [51], describes the isomerization of methyl thiocyanate in the gas phase at 300 – 400°C on a fixed-bed catalyst. The carrier (silica gel, activated charcoal) is impregnated with catalytically active salts, e.g., alkali thiocyanate, $ZnCl_2$. The vapor phase at the head of the reactor contains up to 55 % methyl isothiocyanate. It is purified by fractional distillation and the recovered methyl thiocyanate is recycled.

The production of methyl isothiocyanate from sodium methyldithiocarbamate and hydrogen peroxide has been developed on a large industrial scale [53], [54]. The formation of methyl isothiocyanate takes place via several steps:

$$2CH_3NH{-}\overset{\overset{\displaystyle S}{\|}}{C}{-}SNa + H_2O_2 \longrightarrow \left[CH_3NH\overset{\overset{\displaystyle S}{\|}}{C}{-}S{-}S{-}\overset{\overset{\displaystyle S}{\|}}{C}NHCH_3\right] + 2NaOH$$

$$CH_3HN{-}\overset{\overset{\displaystyle S}{\|}}{C}{-}S{-}S{-}\overset{\overset{\displaystyle S}{\|}}{C}{-}NHCH_3 \longrightarrow 2CH_3{-}N{=}C{=}S + S + H_2S$$

$$H_2S + 4H_2O_2 \longrightarrow H_2SO_4 + 4H_2O$$

The reaction can be represented by the overall equation:

$$2CH_3NH\overset{\overset{\displaystyle S}{\|}}{C}{-}SNa + 5H_2O_2 \longrightarrow 2CH_3{-}N{=}C{=}S + S + Na_2SO_4 + 6H_2O$$

With smaller quantities of hydrogen peroxide, sodium thiosulfate is predominantly formed as the side-product:

$$2CH_3NH\overset{\overset{\displaystyle S}{\|}}{C}{-}SNa + 4H_2O_2 \longrightarrow 2CH_3{-}N{=}C{=}S + Na_2S_2O_3 + 5H_2O$$

Industrial-scale production is as follows: ca. 40 % aqueous sodium methyldithiocarbamate solution (pH 10 – 12) is reacted with 30 – 40 % hydrogen peroxide at ca. 100°C. The pH during the reaction is 3 – 4. The reaction mixture is heated so that the methyl isothiocyanate immediately distils as an azeotrope with water. Methyl isothiocyanate (ca. 5 – 7 %) is dissolved in the water that distils over. This can easily be separated by a short distillation. A very pure product is formed in ca. 85 % yield. The sulfur precipitated during the reaction can be separated readily from the wastewater, which is readily biodegradable. The small quantity of waste-gas formed is incinerated.

Allyl isothiocyanate is produced by reaction of allyl chloride with alkali rhodanides in the two-phase system water/1,2-dichloroethane [66].

All commercial methoxycarbonyl isothiocyanate is produced in situ from methyl chloroformate and potassium thiocyanate in acetone. It is then converted immediately to thiophanate methyl (Section 2.8.2) [67].

Vinyl isothiocyanate can be produced in 63 % yield in a two-step reaction. 2-Aminobromoethane is reacted with thiophosgene in ether. The 2-bromoethyl isothiocyanate obtained after work-up and distillation is converted into vinyl isothiocyanate by elimination of hydrogen bromide [68].

2.5. Quality Specifications and Analysis

The processing of industrially produced organic isothiocyanates to higher-value products and their use in pharmaceuticals requires high purity. The quality of the product is indicated by the −N=C=S content. To determine this, the product is treated with excess dibutylamine in dioxan or chlorobenzene/methanol, and the excess amine is titrated [69], [70]. Gas – liquid chromatography gives a detailed overview of the side-product spectrum.

2.6. Storage and Transport

Methyl isothiocyanate is generally stored in tanks or in 200-kg steel drums. The product is stable to storage, provided it is free of water. The containers should be stored and handled tightly closed at normal temperature in a dry, well-ventilated area, because the product has a severely irritant effect on the skin and mucous membranes and is toxic [71].

Methyl thiocyanate: UN no. 2477, EINECS 209-132-5, IMDG 6.1 PG II, RID/ADR 6.1 no. 20b.

2.7. Commercial Names

Methyl isothiocyanate is sold worldwide by Degussa (Germany) and Morton Chemical (United States).

In formulations, it is sold under the names Trapex and Di-Trapex by Schering. Di-Trapex is sold by Nor-Am under the name Vorlex in the United States. Osmose sells methyl isothiocyanate as MITC-FUME in glass and aluminum ampules. Allyl isothiocyanate is sold in Germany by Haarman & Reimer and in the United Kingdom by Rhône-Poulenc.

2.8. Uses

2.8.1. Methyl Isothiocyanate

Consumption of methyl isothiocyanate is <2000 t/a (1993); 80 % is used in agrochemicals, ca. 15 % in pharmaceuticals, and ca. 5 % in other applications.

Agrochemicals. Methyl isothiocyanate is used directly as a 20 % formulation in an inert solvent (Vorlex, Trapex, Di-Trapex) for protecting soils against fungi and nematodes.

1,3,4-Thiadiazole derivatives are known for their herbicidal properties. Methyl isothiocyanate is used for their synthesis. The most important examples are Spike (Eli Lilly, United States) [72], Ustilan (Bayer, Germany) [73], and Erbotan (Ciba-Geigy, Switzerland) [74].

Spike	R = *t*-butyl
Ustilan	R = ethylsulfonyl
Erbotan	R = trifluormethyl

Pharmaceuticals. Methyl isothiocyanate is an important basic chemical for the synthesis of the H_2-blockers ranitidine (Zantac, Glaxo) [75], [76] and cimetidine (Tagamet, Smith Kline & French) [77].

5-Mercapto-1-methyltetrazole is obtained by treating methyl isothiocyanate with sodium azide. It is a side-group in the cefalosporin antibiotics Latamoxef [78] and Cefamandol [79].

Other Uses. Methyl isothiocyanate is very effective in the protection of wood against rotting [80] and premature decay.

A special application of decay prevention for telegraph poles in the United States has been developed by Osmose Wood Preserving. Four holes, on average, are bored at an angle of 45° in the poles. Ampules of methyl isothiocyanate (MITC-FUME) are inserted into the holes and the latter are closed with wood plugs. The methyl isothiocyanate diffuses slowly into the wood. After ca. 30 d the substance can be detected at 60 – 80 cm from the opening of the ampule in dry Douglas pine [81]. The moisture content of the wood determines the rate of migration, the effectiveness, and also the time at which further treatment is required. The decision as to whether a secondary impregnation with MITC-FUME is necessary is made on inspection of the poles after 6 years [82]. Effectiveness is estimated to last 12 years, so that the second inspection cycle is within the expected period of activity. The lifetime of the telegraph poles is expected to be

doubled by subsequent treatment with MITC-FUME [83].

2.8.2. Other Organic Isothiocyanates

Allyl isothiocyanate is mainly used in the sugar industry because of its fungicidal properties. It protects sugar beet from fungi during storage [84]. Allyl isothiocyanate is also known as an insecticide and an antimicrobial agent, and is used in perfumes. It is used for combatting the cabbage maggot fly *H. brassicae* .

2-(Hydroxyethyl)allylthiourea, produced from allyl isothiocyanate, has been used for producing light-sensitive paper. Methoxycarbonyl isothiocyanate [67], [85] is treated in situ with *o*-phenylenediamine to give thiophanate methyl (→ Fungicides, Agricultural). Thiophanate methyl [*23564-05-8*] is a systemic fungicide, sold under the names Topsin M (Nippon Soda, Japan), Mildothane (May & Baker, United Kingdom), and Cycosin (American Cyanamid, United States). In 1980, United States consumption of thiophanate methyl was 150 t.

2.9. Toxicology and Industrial Hygiene

As vapors, organic isothiocyanates have a severely irritant effect on the skin, eyes, and respiratory tract. Direct contact with the body leads to severe damage to the areas affected. Skin resorption is possible. Oral administration leads to general disturbance of function, cramp, and unconsciousness. Acute toxicity after oral administration in animals is generally high (Table 4).

Methyl Isothiocyanate [86–88]. The vapor has a severely irritant effect on the skin and mucous membranes of the eyes and respiratory tract, and gives rise to a burning pain. On dermal contact, first- or second-degree acid burns are possible. Without immediate treatment, corneal opacity of the eyes is also possible. After swallowing, burning, pain, vomiting, cramp, unconsciousness, complete loss of reflexes, reduction in blood pressure, and death can occur. Methyl isothiocyanate can damage the liver and kidneys and cause lung edema.

Allyl Isothiocyanate [89]. Local and systemic toxic effects are very similar to those of methyl isothiocyanate.

2.10. Safety Measures and Processing Advice

In all work with organic isothiocyanates a protective mask with combination filter B, thick protective clothing, and safety glasses must be worn. Work areas must be well ventilated and, because sight can be impaired in the event of an accident, straight-line, free escape routes must be provided. Apparatus and opened vessels must be extracted while filling and emptying. Vapors form explosive mixtures with air, so ignition sources must be excluded.

Methyl isothiocyanate which has leaked must be covered with cold water, and the crusts formed added in portions to 10 % aqueous ammonia, and disposed of separately. Spilled allyl isothiocyanate should be covered with activated charcoal and the latter disposed of carefully.

2.11. Ecological Aspects

Organic isothiocyanates, particularly methyl and allyl isothiocyanates, represent a hazard to bodies of water. Measures should be taken

Table 4. Toxicological data for organic isothiocyanates

Name	RTECS	Administration route	Species	LD_{50}, mg/kg
Methyl isothiocyanate	PA 9625000	oral	rat	67
		dermal	rabbit	174
		inhalation	rat	29.6
Allyl isothiocyanate	NX 8225000	oral	rat	112
		dermal	rabbit	88
Phenyl isothiocyanate	NX 9275000	oral	mouse	87

to avoid contamination of lakes, streams, and groundwater, under all circumstances.

1. Introduction

Thiocyanates are the salts of thiocyanic acid, H−S−C≡N. The older name, rhodanides, is still used in many countries. Although HSCN, which is unimportant industrially, is readily decomposed, thiocyanates are stable both in solution and in the crystalline state. Some chemical reactions of thiocyanates are similar to those of halides. One of their characteristic reactions is the blood red coloration they give with the iron(III) ion. Pure thiocyanate solutions are titrated using the Volhard method in nitric acid against 0.1 N silver nitrate with iron alum as indicator.

The older production methods for thiocyanates were based on the use of coke oven gas, which used to be in plentiful supply. These very economical methods have become less important over recent decades because of higher quality requirements for the final product and the availability of suitable alternative processes.

Thiocyanates, in particular the sodium and ammonium salts, are mainly used as raw materials or auxiliaries in fiber production, for agricultural products, in photography, in the chemical industry, and in building. The realization that thiocyanates play an important role in many biochemical processes in animals and humans [1] has been increasingly exploited in the production of personal hygiene products and in the foodstuffs and pharmaceutical industries.

2. Thiocyanates

2.1. Ammonium Thiocyanate

Properties. Ammonium thiocyanate [*1762-95-4*], NH_4SCN, M_r 76.12, ϱ 1.305 g/cm^3, is a white, hygroscopic salt which forms stable monoclinic crystals below 90 – 92 °C [2], [3]. At higher temperatures it is converted to the rhombic form. The *mp* of the pure salt is 149 °C. If it is heated to above 100 °C it partially rearranges to the isomeric thiourea.

The degree of rearrangement depends on the temperature and the heating time. Lower temperatures and longer heating times give the highest proportion of thiourea [4]:

200 h at 122 °C	31.7 mol % $SC(NH_2)_2$
10 – 15 h at 150 °C	28.0 mol % $SC(NH_2)_2$

If the melt is further heated to 180 – 200 °C, guanidinium thiocyanate is formed [5].

$$2\,NH_4SCN \longrightarrow [H_2N{=}C(NH_2)_2]SCN + H_2S$$

Here, CS_2, NH_3, and – via the intermediate melamine – a compound with the formula $C_6H_3N_9$ are formed as byproducts.

Ammonium thiocyanate is readily soluble in many polar solvents. The solubilities in 100 g solvent are for liquid ammonia (25 °C) 312 g, for liquid sulfur dioxide (0 °C) 46.8 g, and for acetonitrile (18 °C) 7.5 g. Ammonium thiocyanate is readily soluble in ethanol and acetone.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a26_759

The density of aqueous NH_4SCN solutions (in kg/L) is as follows:

15 % NH_4SCN	1.033
30 % NH_4SCN	1.068
45 % NH_4SCN	1.103
60 % NH_4SCN	1.140

and the solubility at various temperatures (in wt %):

0 °C	55.0
30 °C	66.8
60 °C	77.8
90 °C	87.5

The boiling point of a 30 % solution in water is 105 °C, of a 50 % solution 110 °C, and of an 80 % solution 140 °C.

The enthalpy of solution in water is 23.86 kJ/mol. By mixing 100 g water with 130 g ammonium thiocyanate a temperature decrease of 18 °C can be achieved (cooling baths). As the salt of a weak base ammonium thiocyanate is weakly acidic in aqueous solution. The pH value of a 5 % solution is between 4.8 and 5.0.

Since small quantities of iron in ammonium thiocyanate which has been exposed to light can cause the typical red coloration, attention must be paid to the chemical resistance of vessels used for storage or processing. Aqueous ammonium thiocyanate solutions and crystals severely corrode mild and stainless steels up to and including the grade 1.4301. The stainless steels 1.4571 (UNS S31635) and 1.4404 (UNS S31603) have limited resistance. Only austenitic steels with a molybdenum content of over 4 % or a high nickel content, such as 1.4449/1.4439 (UNS S31726), 1.4539 (UNS N08904), 2.4858 (UNS N08825) and 1.4563 (UNS N08028), have corrosion rates of < 10 µm per year up to 80 °C in concentrated ammonium thiocyanate solution.

Glass, titanium, and rubber or baked enamel linings have also proved to be suitable materials. Plastics, such as polypropylene, poly(vinyl chloride), polyvinylidene fluoride, and PTFE, and epoxy, polyester and vinyl ester resins also show good chemical resistance towards ammonium thiocyanate. Tests have shown that small changes in the chemical compositions of the solutions arising, for example, from differences in origin or pH cause changes in the corrosion behavior with metals.

Production. Ammonium thiocyanate is obtained from CS_2 and NH_3 or from the reaction of hydrogen cyanide or cyanides with sulfur and/or polysulfides.

Production from Ammonia and Carbon Disulfide. This continuous, pressure-free process is carried out in two steps [6]. In the first step CS_2 and ammonia gas are reacted in the presence of water over activated charcoal at ca. 50 °C in an interface reactor to give ammonium dithiocarbamate.

The latter is decomposed in the second step at 95 – 100 °C on activated charcoal.

If the NH_3 and CS_2 used are of high purity, the 35 – 45 % ammonium thiocyanate solution formed can be marketed after concentration without further purification. The crystals, which are produced by vacuum evaporation and centrifugation, are of higher purity. In this process, apart from H_2S and excess CS_2, no other waste substances are formed. After CS_2 and H_2S have been separated, the former can be recycled and the latter can be used, for example, for sulfur production in the Claus process. There is also a one-step variant of this process in which the reaction of NH_3 with CS_2 and decomposition take place at ca. 115 °C and 5 bar [7].

Production from Hydrogen Cyanide contained in Coke Oven Gas. Cooled coke oven gas, which has been freed from tar, contains HCN, NH_3, and H_2S. NH_3 and H_2S are reacted with an aqueous slurry of sulfur in a circulating gas scrubber forming $(NH_4)_2S$, which dissolves the elemental sulfur to form ammonium polysulfide. At the same time the HCN combines with the NH_3 dissolving in the washing liquid to give NH_4CN, which then reacts with the polysulfide to give ammonium thiocyanate and ammonium sulfide.

$$(NH_4)_2S_2 + NH_4CN \longrightarrow NH_4SCN + (NH_4)_2S$$

The ammonium sulfide is distilled off. A 25 – 50 % ammonium thiocyanate solution remains, which, after purification, is further processed as in the other processes [5], [8], [9].

Production from Hydrogen Cyanide, Aqueous Ammonia, and Sulfur/Ammonium Polysulfide. Hydrogen cyanide is neutralized with aqueous ammonia, and the ammonium cyanide formed is treated with elemental sulfur and/or ammonium polysulfide with warming to give ammonium thiocyanate [10].

Commercial Forms and Specifications. Ammonium thiocyanate is generally packed in 25 kg (or 50 lb) sacks with polyethylene liners. It is also transported as a 50 or 55 % solution in tank cars or containers of 1000 kg capacity or plastic drums of 200 – 250 kg capacity. The bulk density of the crystalline product is600 – 700 g/L. Ammonium thiocyanate is not a hazardous substance under the terms of the transport regulations and, because the corrosion rates measured on aluminum and steel (St 37) are less than 6.25 mm/a, aqueous ammonium thiocyanate solutions also need not be declared as hazardous substances for air and sea transport. Specifications for ammonium thiocyanate solutions and crystals are listed in Table 1.

Table 1. Typical specifications for NH_4SCN

Property	Solution (e.g., 50 % in water)	Crystals
Appearance	colorless, clear liquid	crystalline, white
NH_4SCN content	49 – 51 %	min. 99.0 % in dry mass
Water content		max. 1.0 %
pH	4.5 – 6.5	4.0 – 6.0 (5 % solution)
Iron	max. 10 mg/kg	max. 2.0 mg/kg
Iodine consumption	max. 20 mg I/100 g	max. 10 mg I/100 g
Sulfides	max. 1500 mg/kg	max. 800 mg/kg
Chloride		max. 50 mg/kg
Sulfate		max. 200 mg/kg
Density (20 °C)	1.113 – 1.118 g/ml	
APHA number	max. 80	

Uses. Most of the ammonium thiocyanate is produced as an intermediate in the production of other inorganic thiocyanates. It is also used as the starting material for compounds such as aminothiazoles [11].

Large quantities of ammonium thiocyanate are used in agriculture. It is used to combat worms in cattle and, as a mixture with aminotriazole, reinforces the activity of the latter as a broad-spectrum herbicide. Ammonium thiocyanate is also used as a raw material for the production of other herbicides, such as diallates, triallates and tricyclazoles. It is also used as a raw material for fungicides, such as methyl isothiocyanate.

Ammonium thiocyanate is extensively used in photography as an accelerator with sodium thiosulfate in fixing baths, where it removes undeveloped silver (Ag^+). Addition of ammonium thiocyanate to electrolytic cells in the production of ammonium peroxodisulfate, $(NH_4)_2S_2O_8$considerably increases the yield.

Ammonium thiocyanate is used as a solvent for cellulose [12–14], which can also be spun [15]. In the textile industry ammonium thiocyanate is widely used to improve desired properties:

1) In dyeing [16] and improving the quality [17], [18] of cotton
2) For improving the resistance of silk to creasing, light, and wear and tear [19], [20]
3) For lowering the absorption capacity of marks on nylon floor coverings [21]
4) For softening jute fibers [22]
5) For the heat-stabilization of polyester fibers [23]
6) In printing [24] or dyeing [25] fabrics

In the steel industry ammonium thiocyanate is used for coating [26], [27] and as a corrosion inhibitor against acidic gases [28]. It is used as an additive for silver [29] and tin [30] plating baths and for etching aluminum [31].

Because of the neutron-absorbing properties of hafnium, only hafnium-free zirconium can be used in nuclear technology. Following their extraction, Zr and Hf are dissolved in aqueous ammonium thiocyanate so that the $Hf(SCN)_4$ complex can subsequently be extracted with an organic solvent.

Ammonium thiocyanate can also be used as a component in the following applications:

1) For energy storage in combination with heat pumps [32–35]
2) In vulcanization [36], [37]
3) For the production of fire-extinguishing agents [38]

4) In absorbents for ammonia [39] or steam [40]

2.2. Sodium Thiocyanate

Sodium thiocyanate [*540-72-7*], NaSCN, M_r 81.08, and its dihydrate [*1702-40-5*], $NaSCN \cdot 2\,H_2O$, M_r 117.11, form white crystals. The hygroscopic NaSCN crystal is orthorhombic [41]. An α- and a β-form of monoclinic $NaSCN \cdot 2\,H_2O$ are known [42]. The density of $NaSCN \cdot 2\,H_2O$ is 1.56 g/cm^3. On recrystallization the crystals have a severe tendency to agglomerate if residual moisture content is above ca. 0.3 – 0.5 %, particularly in the case of high-purity NaSCN. Anhydrous NaSCN melts at 287 °C and the dihydrate dissolves in its own water of crystallization at 30.4 °C.

The solubility of NaSCN in water (in wt %) at various temperatures is:

30.4 °C	63.2
60 °C	65.2
90 °C	67.3

and the density (in kg/L):

40 wt % NaSCN	1.228
50 wt % NaSCN	1.298
55 wt % NaSCN	1.333

The solubility increases sharply up to the triple point (30.4 °C) and thereafter only gradually. The *bp* of a 20 % solution in water is 107 °C, of a 40 % solution 115 °C, and of an 80 % solution 140 °C. The solubility of sodium thiocyanate in methanol increases from 26 – 35 % over the temperature range 16 – 52.5 °C, that in ethanol from 15.5 – 19.6 % at 19 – 71 °C, and that in acetone from 6.4 – 17.5 % at 18.8 – 56 °C. Sodium thiocyanate is less corrosive than ammonium thiocyanate. Besides the materials named under ammonium thiocyanate (see Section 2.1), aluminum and 1.4571 steel (UNS S31635) are also resistant.

Production. Sodium thiocyanate can be obtained by using the process described for ammonium thiocyanate from CS_2 and NH_3, but substituting 1 mol NH_3 with 1 mol NaOH (50 % solution) [43].

$$CS_2 + 3\,NH_3 + NaOH \longrightarrow NaSCN + (NH_4)_2S + H_2O$$

If ammonium thiocyanate is available and it is possible to use the ammonia formed, sodium thiocyanate can be produced by treating ammonium thiocyanate with sodium hydroxide. This process can also be carried out continuously in a column.

$$NH_4SCN + NaOH \longrightarrow NaSCN + NH_3 + H_2O$$

In another process sodium cyanide formed by neutralizing HCN with NaOH, is treated with rhombic sulfur and/or sodium polysulfide to give sodium thiocyanate [44], [45]. The sulfur can also be added as a suspension in ethanol [46].

Sodium thiocyanate is also formed when wastewater from desulfurization plants for coke-oven gas is treated with NH_3, NaOH, and $Ca(OH)_2$ [47].

Like ammonium thiocyanate, sodium thiocyanate is formed as an aqueous solution which may be evaporated after purification to higher concentrations or to give crystals. If the evaporation to form crystals takes place above 30.4 °C the anhydrous salt is formed, and below this temperature the dihydrate.

Table 2. Typical specifications for NaSCN

Property	Solution (e.g., 50 % in water)	anhydrous crystals
Appearance	colorless, clear liquid	crystalline, white
NaSCN content	49 – 51 %	min. 99.0 % in dry mass
Water content		max. 3.0 %
pH	7.5 – 9.5	5.5 – 7.5 (5 % solution)
Iron	max. 1.0 mg/kg	max. 2.0 mg/kg
Iodine consumption		max. 20 mg I/100 g
Sulfides	max. 80 mg/kg	max. 15 mg/kg
Chloride		max. 100 mg/kg
Sulfate		max. 200 mg/kg
Ammonium (as NH_3)	max. 300 mg/kg	max. 200 mg/kg
Density (20 °C)	1.291 – 1.305 g/ml	
APHA number	max. 40	

Commercial Forms and Specifications. Sodium thiocyanate is packed as the anhydrous salt and as the dihydrate in 25 (or 50) kg sacks with polyethylene liners. The 50 or 55 % solutions are dispatched in tank cars or containers of 1000 kg capacity or in 250 kg plastic drums. Sodium thiocyanate is not classified as a hazardous substance in transport regulations, and

because the corrosion rates measured on aluminum and steel (St 37) are less than 6.25 mm/a, aqueous sodium thiocyanate solutions need not be declared as hazardous substances for air and sea transport. For the specifications for sodium thiocyanate solutions and crystal form, see Table 2.

Uses. Much of the sodium thiocyanate produced is used in polyacrylonitrile fiber production. Since the decomposition of polyacrylonitrile begins below its melting point, spinning the melt is not possible. However, polyacrylonitrile can be processed to give fibers when dissolved in aqueous sodium thiocyanate solution in the presence of additives. In a similar process polyacrylonitrile is dissolved in an organic solvent.

Sodium thiocyanate is used in the chemical industry as raw material for the production of organic isothiocyanates [48], such as methyl isothiocyanate, other monoalkyl isothiocyanates, or thiosemicarbazides. Some of these products are used as pesticides. Fungicides, such as methylene bisthiocyanate (MBT) and 2-thiocyanomethylthiobenzothiazole (TCMTB) are also produced from sodium thiocyanate. Like ammonium thiocyanate, sodium thiocyanate is used in the production of sodium peroxodisulfate ($Na_2S_2O_8$). In many countries sodium thiocyanate has replaced calcium chloride as the additive for reducing the hardening time of concrete. However, as the corrosive action of thiocyanate on the iron in reinforced concrete cannot be fully explained, there are restrictions in the case of concrete with high-quality requirements and prestressed concrete.

Alkali metal thiocyanates are used in the production of solid cell batteries [49], [50], and in the production of dyes for liquid crystal indicators [51].

Because of complex formation with Fe^{3+} ions, thiocyanates are used as laboratory reagents. The blood red color of $Fe(SCN)_3$ in water is used in oil fields to detect the underground connections between different drillholes. Sodium thiocyanate is also mixed with oil field explosives as a stabilizer. Furthermore, thiocyanates are used in the production of ink for ink-jet printers [52], [53].

In the pharmaceutical industry thiocyanate has been used as an antihypertensive, but the high concentrations required gave rise to side effects. Thiocyanates are used as raw materials for antithrombolytics [54] and antitumor drugs [55], and as components of hair growth preparations. In hair dyeing, thiocyanates reduce the duration of the treatment [56], [57].

In recent decades sodium thiocyanate has increased in importance as a preservative. In the lacto-peroxidase system thiocyanate, together with peroxides, forms hypothiocyanite ($OSCN^-$), which exhibits pronounced antibacterial activity. Fresh cows' milk is protected from immediate degradation by the natural presence of thiocyanate (4 – 6 ppm) and peroxides. In countries where cooling the milk before processing cannot be guaranteed, a further ca. 10 ppm sodium thiocyanate can be added as a preservative together with the oxidizing agent sodium carbonate peroxohydrate ($2\,Na_2CO_3 \cdot 3\,H_2O_2$) [58], [59]. As this method seems to be effective and free of side effects, it is being increasingly used as a means of preservation in the cosmetics industry.

2.3. Potassium Thiocyanate

Potassium thiocyanate [*333-20-0*], KSCN, M_r 97.18, forms colorless, prismatic crystals with *mp* 175 °C [60], [61]. At 20 °C it has a density of 1.89 g/cm^3. The solubility in water at 20 °C is 20.8 g/100 g. It is readily soluble in ethanol.

Potassium thiocyanate is produced by the same processes as sodium thiocyanate, but using KOH instead of NaOH. Potassium thiocyanate is used for some of the same purposes as sodium thiocyanate, but to a lesser extent because of its higher price. Potassium thiocyanate is particularly important as an intermediate and a final product in the pharmaceuticals industry. It is added to toothpastes and mouthwashes to approximately double the quantity of thiocyanate which is naturally present in saliva. In the lacto-peroxidase system it increases the antibacterial activity in combination with peroxides [62–64]. Halides behave similarly, but, unlike thiocyanates, they also cause undesired side effects.

Although the properties of potassium and sodium thiocyanates are comparable, the potassium salt is more corrosive. At the boiling point potassium thiocyanate solutions cause pitting in aluminum and attack 1.4571 stainless steel

(UNS S31635) to the same extent as ammonium thiocyanate. In laboratory tests only 1.4577 and 1.4438 steels (UNS S31703) have corrosion rates of < 10 µm per year. With mild steels potassium and sodium thiocyanates exhibit comparable corrosion rates, which are clearly exceeded by that of ammonium thiocyanate.

2.4. Alkaline Earth Thiocyanates

Of the known alkaline earth thiocyanates only calcium and barium thiocyanates are important industrially. Some properties of these two compounds are given in Table 3.

Table 3. Properties of calcium thiocyanate tetrahydrate and barium thiocyanate trihydrate

Property	$Ca(CSN)_2 \cdot 4H_2O$	$Ba(SCN)_2 \cdot 3H_2O$
M_r	228.31	307.58
mp, °C	ca. 59	ca. 70
Solubility, g/100 g H_2O	ca. 1000 g	ca. 240 g

Besides $Ca(SCN)_2 \cdot 4H_2O$, di- and trihydrates are known.

Calcium and barium thiocyanates are obtained by treating aqueous ammonium thiocyanate solutions with the corresponding alkaline earth hydroxides.

$$M(OH)_2 + 2\,NH_4SCN \longrightarrow M(SCN)_2 + 2\,NH_4OH$$

After the ammonia has been distilled off, the salt solutions are evaporated under reduced pressure, and the salt crystals are obtained by centrifugation. They then have an assay of 97 – 98 % based on the hydrate. The yield is almost quantitative.

Calcium and barium thiocyanates [and also strontium thiocyanate $Sr(SCN)_2$] can also be produced from NH_4SCN, NH_3, and CS_2 with the corresponding metal hydroxide [43]. Calcium thiocyanate can also be obtained from the wastewater produced in the desulfurization of coke-oven gas, together with NH_3 and $Ca(OH)_2$ [65].

Calcium and barium thiocyanates are used in the chemical and pharmaceutical industries. Calcium thiocyanate is used for the production of special materials in the building industry. Barium thiocyanate is used in printing and dyeing textiles.

2.5. Other Thiocyanates

Of the large number of other known thiocyanates, only copper(I), lead(II), and aluminum thiocyanates are important industrially.

Copper(I) thiocyanate [*18223-42-2*], CuSCN, M_r 121.62, is a yellowish-white powder with *mp* 1084 °C and ϱ 2.843 g/cm^3 at 20 °C. It is sparingly soluble in water (5 mg/L). It is soluble in alkali thiocyanate solutions and ether, but not in ethanol. It forms a deep blue copper – ammonia complex in aqueous ammonia.

The industrial production of CuSCN starts from ammonium or sodium thiocyanate. Aqueous solutions of the thiocyanate are warmed with copper sulfate solution. SO_2 or alkali metal sulfites and hydrogensulfites can be used to reduce the copper(II) thiocyanate formed initially.

$$2\,NaSCN + 2\,CuSO_4 + Na_2SO_3 + H_2O \longrightarrow 2\,CuSCN + 2\,NaHSO_4 + Na_2SO_4$$

The CuSCN, which is precipitated quantitatively, is separated from the dissolved sodium salts by decantation and centrifugation, washed until sulfate-free, and dried [66], [67].

CuSCN is used in the production of antifouling agents for protecting the underwater surfaces of ships against vegetation. Anti-fouling paints based on tributyltin (TBT) are only allowed to be used for ships more than 25 m long.

Lead(II) thiocyanate [*592-87-0*], $Pb(SCN)_2$, M_r 323.38, forms white to pale yellowish, monoclinic crystals with *mp* 190 – 195 °C (decomp.) and ϱ 3.82 g/cm^3 at 20 °C. The solubility in water at 20 °C is ca. 0.05 g/100 g, and increases on warming. Lead(II) thiocyanate dissolves in nitric acid, aqueous ammonia, and alkali metal thiocyanate solutions.

Lead(II) thiocyanate is produced by treating water-soluble lead salts (e.g., lead nitrate) with alkali metal thiocyanate solutions [68].

Lead(II) hydroxythiocyanate, Pb(OH)(SCN), can be obtained by boiling a slurry of $Pb(SCN)_2$ in water or by the action of basic lead(II) acetate hydroxide on $Pb(SCN)_2$ [69].

Lead(II) thiocyanate is used for producing fuses in the explosives industry and, together with antimony sulfide and potassium chlorate, for producing phosphorus-free matches.

Aluminum thiocyanate, $Al(SCN)_3$, M_r 201.21, can be produced as a ca. 30 % aqueous solution by treating an aluminum sulfate solution with barium or calcium thiocyanate. After separation of the alkaline earth sulfate, the $Al(SCN)_3$ solution can only be evaporated under reduced pressure to a concentration of ca. 30 %. Above this concentration the $Al(SCN)_3$ begins to decompose. $Al(SCN)_3$ solutions are used as mordants in alizarin printing in the textile industry.

3. Thiocyanic Acid

Properties. Thiocyanic acid, formerly also known as hydrogen rhodanide, HSCN, M_r 59.09, *mp* 5 °C, is a colorless, very volatile liquid. It is readily soluble in water and behaves as a strong mineral acid. In very dilute (max. 5 %) aqueous solutions thiocyanic acid is relatively stable up to 20 °C. At higher temperatures or at higher concentrations it polymerizes with loss of hydrogen cyanide, forming 5-imino-1,2,4-dithiazolidine-2-thione.

Production. Anhydrous thiocyanic acid is obtained as white crystals by passing dry H_2S into dry $Hg(CN)_2$. Pure, gaseous thiocyanic acid can be produced by heating a mixture of KSCN and $KHSO_4$ in H_2 under reduced pressure (ca. 60 mbar) [69]. Aqueous solutions of thiocyanic acid are obtained by decomposing a 25 % ammonium thiocyanate solution with dilute sulfuric acid.

$$NH_4SCN + H_2SO_4 \longrightarrow HSCN + NH_4HSO_4$$

The yield is almost quantitative when stoichiometric quantities of the starting materials are used. The thiocyanic acid liberated is distilled at ca. 30 mbar and collected in water. The industrial and economic importance of free thiocyanic acid is low.

4. Economic Aspects

The annual worldwide demand for thiocyanates is ca. 15 000 t, based on 100 % crystalline product. As industry mainly uses sodium and ammonium thiocyanates, these account for by far the greatest part of the overall requirement. About 20 % of the thiocyanate is used in North America and 35 % in Western Europe.

Around 30 – 40 % of the thiocyanate is used in fiber production. The second largest consumer (ca. 20 %) is the production of agricultural auxiliaries. About 15 % is used in photography. Of the many other uses, application as a reagent for extracting metals such as copper, molybdenum, nickel, lead, zinc, and zirconium from ores is important.

The world market for thiocyanates appears to be relatively stable to slightly recessive. Decreases in the use in agricultural products in the early 1990s were only partially compensated for by a slight increase in the requirement for the photography industry.

The largest producers in order of importance are Western Europe (Germany and the United Kingdom), South East Asia (Japan and China), and the United States.

5. Toxicology

Thiocyanates are only slightly toxic. Most inorganic thiocyanates have been assigned to toxicity classes 3 – 5 according to the Swiss toxicity law. In animal experiments the lethal dose (LD_{50}) has been found to be 50 – 15 000 mg/kg [70]. Ammonium thiocyanate with an LD_{50} of 500 mg/kg was assigned to toxicity class 3, and sodium thiocyanate with LD_{50} 764 mg/kg to class 4. The NOEL for rainbow trout for NH_4SCN is 100 mg/L, and the EC_{10} value for bacteria (*Ps. putia*) is 8 g/L. Although resorbed thiocyanate is biologically degradable, degradation can become problematic at high concentrations ($>$ 36 mg SCN^-/L H_2O).

On handling thiocyanates skin contact should be avoided, as prolonged contact can lead to skin irritation and rashes, and thiocyanates are readily resorbed.

The action of strong acids on thiocyanates can liberate toxic hydrogen cyanide. Ammoni-

um and sodium thiocyanates have been assigned to water hazard class 1 (WGK 1) in Germany (September 1994).

1. Aliphatic Thiols, Sulfides, Disulfides, and Polysulfides

1.1. Introduction

Aliphatic thiols, R – SH, were formerly known as mercaptans because of their affinity for mercury compounds (Latin: *corpus mercurium aptans*). They can be regarded as organic derivatives of hydrogen sulfide or thio analogs of alcohols.

According to IUPAC nomenclature the names of aliphatic thiols are constructed by adding the ending "thiol" to the name of the corresponding alkane (e.g., ethanethiol). If substituents with higher priorities are present, the prefix "mercapto" is used instead (e.g., mercaptoacetic acid).

Thiols are found in a wide range of natural materials. Low molecular mass thiols are responsible for the aromas of various foods, such as cheese, milk, coffee, cabbage, and bread. They are probably liberated during processing through enzymatic cleavage of sulfides, disulfides, and other sulfur-containing substances [12]. Thiols can also be detected in a number of plants [13]. Methanethiol occurs in radishes and various alliums, such as onions, leeks, and garlic. The characteristic odor of fresh grapefruit juice is due to the presence of 1-*p*-menthene-8-thiol in high dilution [14]. Asparagus contains 3-mercapto- and 3,3′-dimercaptoisobutyric acids [15]. Butanethiol and 2-methylbutanethiol have been found in the defense secretions of skunks [16]. Low molecular mass alkanethiols are formed in the degradation of biological material during putrefaction [17], and consequently

are found in varying quantities in most crude petroleum, depending on its origin [18].

L-Cysteine, one of the natural amino acids found in proteins and a substance that participates in an important reversible redox system with the disulfide cystine, is of considerable biochemical interest, as is coenzyme A (CoA−SH), whose acetyl derivative (CoA−S−Ac) is a key participant in the metabolism of carbohydrates, fats, and proteins.

In 1834 W. C. Zeise achieved the first thiol synthesis by preparing ethanethiol from barium hydrogensulfide and calcium ethyl sulfate [19].

1.2. Properties of Aliphatic Thiols

1.2.1. Physical Properties

With the exception of methanethiol, which is gaseous at room temperature, aliphatic thiols with up to 16 carbon atoms are colorless or yellowish liquids. They are characterized by extremely offensive odors, perceptible even at very high dilution. The odor threshold for ethanethiol is less than 0.001 ppm, and that for the *S*-enantiomer of 1-*p*-menthene-8-thiol is only 2×10^{-8} ppm [13]. The odor sensitivity is highly concentration dependent, however, particularly for the lower thiols. At very low concentrations the C_1 to C_4 thiols have an odor similar to that of coal gas. That of other low molecular mass thiols has been described as pleasantly fresh or fruity, but at higher concentrations these compounds have extremely nauseous odors.

The bond energy of the S−H bond (339 kJ/mol) is lower than that of the O−H bond (462 kJ/mol), so hydrogen bonding to sulfur is also much weaker than to oxygen. This in turn means that thiols are less highly associated than the corresponding alcohols, as manifested in higher volatilities and lower boiling points for simple aliphatic thiols compared with their oxygen counterparts. This boiling point difference diminishes as the chain length increases, however, and is eventually reversed. Thus, from 1-octanethiol onward the straight-chain thiols have higher boiling points than the corresponding alcohols (Fig. 1).

The physical properties of important alkanethiols are summarized in Table 1. The high flammability of thiols containing up to six carbon atoms is particularly noteworthy. All the corresponding flash points lie below room temperature.

Figure 1. Comparison of boiling points for *n*-alcohols and *n*-thiols containing 1 – 10 carbon atoms
—- RSH – – – – ROH

Unlike their oxygen analogs, aliphatic thiols are only slightly soluble in water, but they are readily soluble in hydrocarbons, ethers, and alcohols. Ethane-, propane-, and butanethiols form azeotropes with aliphatic hydrocarbons, but not with benzene or toluene.

Aliphatic thiols are only weakly acidic, but they are significantly more acidic than the corresponding alcohols, which explains the ready solubility of low molecular mass alkanethiols in dilute base. However, the solubility decreases sharply with increasing molecular weight.

$$R-SH + Na^+OH^- \longrightarrow R-S^-Na^+ + H_2O$$

The resulting thiolate salts, RS^-Na^+, are less basic but more strongly nucleophilic than the equivalent alkoxide salts.

1.2.2. Chemical Properties

Salt Formation. Aliphatic thiols form thiolates (formerly known as mercaptides) with numerous metal cations. Many of these salts are sparingly soluble, so their formation can be used for the qualitative and quantitative determination of thiols. Many mercury thiolates, $Hg(SR)_2$, have been used for the identification of thiols because of their defined melting points. Silver thiolates have also been used for the qualitative and quantitative detection of thiols. The formation of lead thiolate constitutes the basis for the "doctor test," a method of determining the thiol content of crude petroleum. Heavy metals, in particular mercury and cadmium, can be removed from

wastewater with SH-group-containing resins or ion exchangers [20].

Thiolate formation is also utilized in the treatment of heavy-metal poisoning (copper, lead, mercury, zinc, cobalt, and gold). The thiol groups of essential enzymes that have been blocked by such metal ions are liberated again with the aid of the more strongly chelating thiols. The water-soluble substances 2,3-dimercaptopropane-1-sulfonic acid [*4076-02-2*] and dimercaptosuccinic acid [*304-55-2*] are being increasingly used for this complexation reaction, alongside 2,3-dimercapto-1-propanol [*59-52-9*], also known as dimercaprol or British Anti-Lewisite (BAL), and penicillamine [*52-67-5*], which have been known for a long time [21]. Mercaptoacrylic acids are also said to be suitable antidotes for lead and nickel poisoning [22]. Zinc and cadmium salts of cylcohexanethiol can be used as catalysts, crop-protection agents, and polymer stabilizers [23]. Certain gold thiolates are used in the treatment of arthritis. Organic antimony thiolates can be used as passivators for catalysts employed in the cracking of hydrocarbons [24]. Thiolate-coordinated transition metals play an important role in many physiological processes [25].

Oxidation. Thiols are readily converted into the corresponding disulfides by mild oxidizing agents.

$$2\,R-SH \underset{\text{Red.}}{\overset{\text{Ox.}}{\rightleftharpoons}} R-S-S-R$$

This facile oxidizability is the basis of quantitative thiol determination, and it is used industrially for sweetening crude-petroleum distillates. In this process the thiol-containing acidic fractions are oxidized with atmospheric oxygen under basic conditions in the presence of such catalysts as cobalt phthalocyanine monosulfonate [26] or EDTA complexes of copper(II) [27] or cobalt(II) [28]. Many other reagents can also be used for oxidizing thiols to disulfides (see Section 1.6.3). The thiol–disulfide redox system also plays an important role in a range of biological processes (glutathione, cysteine–cystine) [29].

Thiols and disulfides are oxidized to sulfonic acids by stronger oxidizing agents via a series of isolable intermediates. These oxidizing agents include nitric acid, potassium permanganate, chlorine gas [30], a mixture of hydrogen peroxide and aqueous hydrochloric acid [31], and atmospheric oxygen in the presence of catalytic amounts of dimethylsulfoxide and hydrogen halide [32].

Addition Reactions. Being strong nucleophiles, aliphatic thiols add to multiple bonds to give thioethers. This reaction, which is also used for the synthesis of unsymmetrical sulfides (see Section 1.6.2), produces a normal Markovnikov adduct (→ Alcohols, Aliphatic,

Chap. 2.3.7.) under ionic reaction conditions and an anti-Markovnikov adduct in the presence of radical-forming agents.

Thiols add to carbonyl compounds in the same way as alcohols. With aldehydes or ketones the products are thioacetals or thioketals [33], and with carboxylic acids and their derivatives they are *S*-esters of thiocarboxylic acids [34]. Other transformations of thiols are described in [35].

1.3. Production of Aliphatic Thiols

1.3.1. From Alcohols

The reaction of hydrogen sulfide with alcohols is used mainly for industrial syntheses of low molecular mass thiols.

$$ROH + H_2S \longrightarrow R\text{–}SH + H_2O$$

Such reactions are carried out in the gas phase> 300 °C, and generally require a catalyst. The thorium oxide [36] once used for this purpose has now largely been replaced by basic catalysts on a carrier of basic aluminum oxide. These catalysts favor thiol formation, whereas disulfides are the main products in acidic medium [37]. Promoters for thiol formation include a range of metal oxides, potassium and sodium tungstates, and heteropolyacids and their salts [37–40]. Thioethers and ethers may form as byproducts, along with olefins (except in the case of methanol).

The method described is used mainly for the industrial production of *methanethiol* [38,41], although ethanethiol is also produced by this route [42]. The method is not suitable for primary thiols with more than three carbon atoms because of the small boiling-point differences between the products and the starting alcohols (see Fig. 1).

Tertiary thiols can be produced in the liquid phase by reacting alcohols with hydrogen sulfide in the presence of sulfuric acid. This method leads to *triphenylmethanethiol* [*3695-77-0*] in 75 % yield [43], and is used industrially to produce *2-methyl-2-propanethiol* (*tert*-butanethiol) [44].

The reaction of alcohols with phosphorus pentasulfide is frequently employed for this purpose as well, and has been patented for alkanethiols [45]. C_4 to C_{16} alcohols are converted in this way into dialkyl dithiophosphates, which give the corresponding thiols on acid hydrolysis.

A more recent method uses Lawesson's reagent [*19172-47-5*] for the conversion of alcohols into thiols [46].

Lawesson's Reagent

1.3.2. From Alkenes

A second industrially important process for aliphatic thiol production is the addition of hydrogen sulfide to alkenes. In principle, both Markovnikov (**i**) and anti-Markovnikov (**ii**) adducts can result from this reaction, but formation of one isomer or the other can be favored by the use of suitable catalysts.

The Markovnikov product (**i**) is formed preferentially under ionic conditions in the presence of oxides, sulfides, acids, or elemental sulfur. Branched alkenes react more rapidly than straight-chain or terminal alkenes. Secondary thiols are prepared by the addition of hydrogen sulfide to linear alkenes in the presence of acid catalysts [47]. The analogous reaction of branched alkenes to give tertiary thiols is catalyzed by aluminum chloride, Al/Si oxides [48], zeolites [49], or cation exchange resins [50].

This method is exploited for the industrial production of a variety of thiols. Reaction is carried out in either the gas or liquid phase depending on the catalyst used. The yield of thiol increases with excess hydrogen sulfide (3 –10 mol

per mole of alkene), high pressure (≤ 7 MPa), and relatively low reaction temperature. Dialkyl sulfides are formed as byproducts. *Ethanethiol* is prepared from ethylene and hydrogen sulfide in the gas phase over aluminum oxide catalysts containing potassium tungstate [51] or nickel and tungsten oxides [52]. *Cyclohexanethiol* is obtained with cyclohexene and hydrogen sulfide in the gas phase over nickel sulfide on silica gel [53]. The reaction of cyclohexene with hydrogen sulfide over cobalt molybdate has also been described [54]. The industrial production of "*tert*-dodecyl mercaptan," a mixture of isomeric thiols, starts from oligomers of isobutylene or propylene. In the presence of hydrogen sulfide and a boron trifluoride catalyst, "*tert*-dodecyl mercaptan" can be prepared from triisobutylene at $-40\,^{\circ}$C [41] and from propylene tetramer at $60\,^{\circ}$C [55]. Aluminum chloride [41], ethyl aluminum dichloride [56], a mixture of boron trifluoride with phosphoric acid and a low molecular weight alcohol [57], and sodium oxide on zeolite [58] have also been described as catalysts. The industrial production of *2,4,4-trimethyl-2-pentanethiol* is similar to that of *tert*-dodecyl mercaptan. Terpenes are also used as industrial starting materials in this reaction. Thus, 1-*p*-menthene-8-thiol [*71159-90-5*], a component of the grapefruit aroma, is obtained selectively and in high yield by the addition of hydrogen sulfide to limonene in the presence of inorganic Lewis acid catalysts [59].

Electron-withdrawing groups, such as the carbonyl, cyano, nitro, carboxyl, or ester functions, activate alkenes toward nucleophilic addition of hydrogen sulfide. Basic catalysts are particularly suitable for these reactions, including amines [60], anion exchange resins [61], and magnesium oxide [61].

$$CH_2{=}CH{-}X + H_2S \xrightarrow{\text{base}} HS{-}CH_2{-}CH_2{-}X$$

$$X = -CO{-}CH_3,\ -CN,\ -NO_2,\ -COOH,\ -COOR$$

Formation of the anti-Markovnikov product (**ii**) results from a radical addition of hydrogen sulfide to alkenes (→ Hydrogen Sulfide, Chap. 3.3.2.). In industry this reaction is usually initiated with UV light ($\lambda = 253.7$ nm) [62, 63]. Longer wavelength radiation ($\lambda = 300 - 400$ nm) can also be used in the presence of photosensitizers [62–64]. Among the chemical radical initiators, azobisisobutyronitrile is particularly suitable [65]. This can also be used in the presence of accelerators, such as organic phosphines or phosphites [66]. Peroxides, on the other hand, can oxidize the hydrogen sulfide to elemental sulfur, which then acts as a catalyst for the ionic reaction pathway (see above) [67].

The method described is used mainly for the industrial production of primary thiols. The formation of dialkyl sulfides as byproducts is minimized by ensuring that excess hydrogen sulfide is present. Thus, *ethanethiol* is obtained from ethylene and hydrogen sulfide in the liquid phase in the presence of azobisisobutyronitrile and tributylphosphine [68]. *1-Dodecanethiol* is prepared by photochemically catalzyed addition of hydrogen sulfide to 1-dodecene. The olefin is reacted with a five-fold excess of hydrogen sulfide in the presence of α,α-diethoxyacetophenone as initiator at 45 °C and 3 MPa [63]. The industrial preparation of *1-octanethiol* is similar to that of 1-dodecanethiol.

1.3.3. Other Production Methods

Other methods for the industrial-scale preparation of thiols include the reductive thiolation of carbonyl compounds, epoxide ring-opening with hydrogen sulfide, and nucleophilic substitution of alkyl halides or tosylates.

Aldehydes and ketones are reduced to thiols by hydrogen sulfide and hydrogen in the presence of metal sulfides [69]. This process is used for the industrial production of cyclohexanethiol [70].

$$\overset{\backslash}{\underset{/}{C}}{=}O + H_2 + H_2S \xrightarrow{\text{cat.}} \overset{\backslash}{\underset{/}{C}}H{-}SH + H_2O$$

Base-catalyzed cleavage of epoxides with hydrogen sulfide gives mercaptoalcohols. Symmetrical bis(1-hydroxyalkyl) sulfides are formed as byproducts. Inorganic bases, amines and anion exchange resins, zeolites [71], or guanidine [72] can be used as catalysts. In industry, preparation of *mercaptoethanol* [*60-24-2*] by addition of H_2S to ethylene oxide is catalyzed by either a cation exchange resin [73] or the byproduct thiodiglycol [74].

$$H_2C{-}\underset{O}{CH}{-}R + H_2S \xrightarrow{\text{base}} H_2\underset{HS}{C}{-}\underset{OH}{CH}{-}R$$

The reaction of alkyl halides or tosylates with metal hydrogensulfides is frequently used to prepare thiols on a laboratory scale [75].

$$R-X + M-SH \xrightarrow[-MX]{} R-SH$$

X = Cl, Br, I, –O-tosyl

Alcohols are the usual solvents. The competing formation of sulfide can be suppressed by the presence of hydrogen sulfide or sulfuric acid. Sulfide formation is also strongly inhibited in the reaction of alkyl halides with a mixture of hydrogen sulfide and ammonia or alkylamines [76]. C_2 to C_{12} alkanethiols form in essentially quantitative yield from the corresponding bromides and sodium hydrogensulfide in dimethylsulfoxide [77]. The nucleophilic substitution reaction is used industrially to produce *1-dodecanethiol* from 1-chloro- or 1-bromododecane [78].

Substitution of – SH for chlorine occurs particularly readily if the process is activated by the presence of electron-withdrawing groups (e.g., C=O, C≡N) or heteroatoms (O, S, Si) in the α-, β-, or γ-positions [79]. This method is used to prepare mercaptocarboxylic acids and thiols containing additional functional groups [79, 80].

$$Cl-(CH_2)_n-COOH \xrightarrow[2)\ HCl]{1)\ NaSH} HS-(CH_2)_n-COOH$$

$$Cl-CH_2CH_2-O-R \xrightarrow{NaSH} HS-CH_2CH_2-O-R$$

Besides the processes commonly used in industry for thiol production, a number of generally applicable laboratory methods are also available, such as the reaction of an alkyl halide with thiourea, thiosulfate, or dithio- or trithiocarbonate. Details of these methods can be found in the general literature.

1.4. Construction Materials, Storage, and Transport

Manufacturing plant and transport facilities for thiols are preferentially made from (coated) normal steel, stainless steel, aluminum, or copper-free alloys. Thiols in containers made of carbon steel should be handled dry and under a blanket of protective gas to prevent the formation of pyrophoric iron – sulfur complexes. Copper and copper-containing alloys are not suitable for use because they are rapidly attacked by thiols.

Stringent demands apply to the impermeability of thiol piping systems. Seals are normally based on asbestos or fluoroplastics.

Regulations in force with respect to the transport of industrially important thiols are summarized in Table 2.

Table 2. Transport restrictions applicable to aliphatic thiols

Thiol	ADR/RID		IDMG Code	
	Class	Number		
CH_3-SH	2	3bt	2	UN 1064
C_2H_5-SH	3	18b	3.1/II	UN 2363

t-C_4H_9-SH	3	3b	3.2/II	UN 1228
cyclo-$C_6H_{11}-SH$	3	31c	3.3/III	UN 3054
n-$C_8H_{17}-SH$	3	32c		
n-$C_{12}H_{25}-SH$	3	32c		
	6.1	21c		
t-$C_{12}H_{25}-SH$	6.1	21c		

1.5. Uses of Aliphatic Thiols

Many aliphatic thiols are important starting materials for the synthesis of crop-protection agents (especially thiophosphoric acid esters) [81], pharmaceuticals, and polysulfides (see Section 1.6.4). They are also widely used as polymerization regulators in rubber and plastics manufacture. *Methanethiol* is important as a starting material for the industrial production of the amino acid DL-methionine, used as an animal-feed additive. Methanethiol is also used as a gas odorizer, as are other low molecular mass thiols (in particular, ethanethiol). For applications of thiolates and chelate-forming thiols see Section 1.2.2.

Pharmaceuticals. Mercaptoamino acids and their derivatives display a broad spectrum of activity. *N*-Isobutyryl- and *N*-pivaloylcysteine are said to exhibit improved bioavailability compared with *N*-acetylcysteine [*616-91-1*], which is used as a mucolytic [82].

Vanadyl – cysteine complexes can be used for oral treatment of insulin-dependent diabetes [83], and substituted cysteinamides for the localized treatment of inflammatory skin diseases [84]. Certain mercaptoamino acids, such as the 2*S*-enantiomer of 1-(3-mercapto-2-methylpropionyl)-L-proline (Captopril [*62571-86-2*]), act as antihypertensives [85].

Other mercaptoamino acid derivatives have been described as analgetics [86] and antiarthritic agents [87].

Diaminodithiols are chelating agents, and thus useful in radioactive diagnosis [88]. Thiol-substituted dioxolanes [89] and cyclohexenes [90] are mucolytics. Mercapto-substituted propanamides exhibit psychotropic [91] and analgesic activity [91,92].

Agricultural Chemicals. Aminodithiols have been described as effective low-toxicity insecticides [93]. Bismuth dithiolates can be used to combat coccidiosis in poultry and as insecticides [94].

Thiol-substituted 2-propanols are fungicides with low toxicity [95]. Bis(dithiobenzyl)nickel complexes absorb IR radiation and can be used as plant-growth regulators [96].

Other Uses. *N*-Substituted1-amino-2-propylmercaptans are used as antioxidants in lubricating oils [97]. 4-Mercaptobutyramides can act as reducing agents in the permanent waving of hair. They are said to be less toxic and accompanied by less noxious odors than mercaptoacetic acid [98]. Mercaptoalkyl esters of acrylic and methacrylic acids are used as binders for metallic fillings for teeth [99]. Many thiol-substituted terpenes [100], esters [101], ketones [102], and mercaptoalkyloxathiolanes and -oxathianes [103] have been patented as fragrances and aroma substances (e.g., for foods, cosmetics, or pharmaceuticals).

1.6. Alkyl Sulfides, Disulfides, and Polysulfides

1.6.1. Physical and Chemical Properties

Sulfides (R^1-S-R^2) are the sulfur analogs of ethers, and are thus derivatives of hydrogen sulfide. They were referred to previously as thioethers or sulfanes. Alkyl *disulfides* ($R^1-S-S-R^2$) and *polysulfides* ($R^1-S_x-R^2$) are derived from di- and polysulfanes. Symmetrical sulfides contain R groups that are identical ($R^1 = R^2$), whereas unsymmetrical ones have different R groups ($R^1 \neq R^2$). Sulfides are named in the same way as ethers (e.g., diethyl sulfide, methyl phenyl sulfide). Di- and polysulfides are named either as sulfides or as sulfane derivatives (e.g., dimethyl disulfide, diethyltrisulfane). Most low molecular mass alkyl sulfides have intense, unpleasant odors. Organic sulfides and disulfides are widely distributed in natural materials. For example, they occur (together with thiols) in onions and garlic [104], and have been found to be the source of various well-known aromas, including those of asparagus and coffee. In polecats, mink, and skunks such compounds act as pheromones [105]. The cyclic polysulfide lenthionine confers a characteristic odor on cooked mutton and the shiitake mushroom [106]. Many disulfides are components of biologically active substances (e.g., lipoic acid, cystine, holomycin) and physiologically important peptides (e.g., insulin, oxytocin). Here the activity is associated directly with the presence of the disulfide group. Aliphatic sulfides are also present in crude petroleum, accounting for up to 45 % of the total sulfur, but disulfides are virtually absent [107].

Aliphatic sulfides, disulfides, and polysulfides are colorless to yellow or orange liquids. Most are insoluble in water, but readily soluble in ether, acetone, chloroform, and ethanol. Physical data for a few representative compounds are provided in Table 3 (see next page).

Alkyl sulfides, like their oxygen analogs, are very weak bases. Because of nucleophilicity attributable to the free electron pair on sulfur, they form stable addition compounds with halogens and salts of heavy metals. Aliphatic sulfides also form crystalline trialkylsulfonium salts with alkyl halides or dialkyl sulfates.

X = halogen, $O-SO_2-O-R^3$

Depending on the reaction conditions, oxidation of sulfides leads to sulfones or sulfoxides [107]. Sulfonic acids are formed under forcing conditions, and these are then further oxidized to sulfuric acid [108].

Table 3. Physical data for selected alkyl sulfides, disulfides, and polysulfides

Sulfide	CAS registry no.	M_r	*bp*, °C/kPa	d_4^{20}	n_D^{20}	Flash point, °C
$(CH_3)_2S$	[*75-18-3*]	62.13	37.3	0.846	1.4355	−36

Sulfides can be reduced to hydrocarbons or, depending on the reducing agent and the substrate, thiols or hydrogen sulfide.

$$R{-}S{-}R \xrightarrow{\text{Red.}} R{-}H + R{-}SH \xrightarrow{\text{Red.}} 2R{-}H + H_2S$$

The sulfide contraction reaction, a desulfurization with simultaneous C−C bond formation, is important in organic synthesis [109].

Reaction conditions determine whether disulfides are oxidized to thiosulfinic or thiosulfonic acid esters or to sulfonic acids.

The reduction of disulfides to thiols is a reversible reaction of great physiological importance. Hydrogen, zinc in the presence of acid, complex hydrides, or sodium are generally selected as the reducing agents [110]. Disulfides can be reduced selectively with sodium hydrogentelluride in good yield under very mild conditions in the presence of other functional groups [111]. Organic polysulfides can also be reduced to thiols.

1.6.2. Production of Alkyl Sulfides

Many of the procedures for the synthesis of dialkyl sulfides correspond to those for aliphatic thiols, including the alkylation of hydrogen sulfide or alkali metal sulfides with alcohols, alkenes, or alkyl halides to give symmetrical sulfides (Section 1.3). *Dimethyl sulfide*, the industrially most important sulfide, is produced by treating hydrogen sulfide with excess methanol over an aluminum oxide catalyst. Unsymmetrical sulfides are formed in a similar way from thiols and their salts [112, 113], but they can also be obtained by alkylation of thiols with acidic C−H compounds [114]. The alkylation of thiols with alkyl halides in the presence of K_2CO_3 in DMF occurs particularly rapidly, and in almost quantitative yield [115]. Unsymmetrical sulfides can also be made by exchange reactions involving symmetrical sulfides and thiols, catalyzed by phosphotungstic or phosphomolybdic acids [116].

$$R^1{-}S{-}R^1 + R^2{-}SH \xrightarrow{\text{cat.}} R^1{-}S{-}R^2 + R^1{-}SH$$

Cleavage of an epoxide ring with a thiol proceeds analogously to the cleavage with hydrogen sulfide (Section 1.3.3). Bases (such as sodium hydroxide or triethylamine [117]), metal salts (e.g., lithium perchlorate [118]), and acids [119] have all been used as catalysts. The resulting β-hydroxythioethers are important intermediates for a large number of other products.

Alkylthio-substituted carboxylic acids and their thioesters can be prepared from lactones

by treatment with thiols in the presence of an acid catalyst at 100 – 350 °C [120].

The reductive thiolation of carbonyl compounds (Section 1.3.3) can also be carried out with thiols instead of hydrogen sulfide. The borane – pyridine complex in trifluoracetic acid [121] or treatment with boron trifluoride monohydrate followed by triethylsilane [122] can be used to accomplish the reduction.

α-Substituted dialkyl sulfides can be prepared from sulfoxides by means of the Pummerer rearrangement (→ Acetic Anhydride and Mixed Fatty Acid Anhydrides). The deoxygenation of sulfoxides to sulfides is a particularly important approach with respect to asymmetric syntheses. Several methods are known for achieving this reduction [123]. The systems sodium iodide – titanium(IV) chloride [124] and sodium iodide – sulfonic acid [125] are described as especially efficient and mild reagents. The selective reduction of various functionalized sulfoxides can be effected using Lawesson's reagent [126] (see Section 1.3.1).

1.6.3. Production of Alkyl Disulfides

Dialkyl disulfides are often formed as byproducts in the synthesis of sulfides. However, the most important synthetic method is the mild oxidation of thiols. In industry this oxidation is carried out in aqueous alkaline solution using air or oxygen. The reaction is catalyzed by radical initiators (copper, cobalt, nickel, or iron salts, or UV light) [127]. Even high molecular mass disulfides can be prepared in this way [128]. Since in this case water-insolubility of the products can be a disadvantage, the reaction is sometimes carried out in a two-phase mixture in the presence of phase-transfer catalysts [129]. For the oxidation of tertiary thiols a catalyst system consisting of alkali-metal and/or alkaline-earth hydroxides and cobalt molybdate is particularly suitable [130]. The oxidation of thiols with atmospheric oxygen is also exploited industrially for sweetening crude petroleum distillates (see Section 1.2.2).

Other potential oxidizing agents include hydrogen peroxide, halogens (in particular, iodine) [131], and potassium hexacyanoferrate(III) [132]. The fire hazard is lowered and the yield of dialkyl disulfide increased using carbon tetrachloride in aqueous alkali as the oxidizing agent together with a phase-transfer catalyst [133].

Interest has been shown in the oxidation of thiols with nitrogen oxides. Whereas symmetrical sulfides are obtained in good yields with nitric oxide and nitrogen dioxide [134], dinitrogen tetroxide leads first to thionitrites [135], which may then react with an additional equivalent of thiol to give symmetrical or unsymmetrical disulfides [136].

The analogous coupling of thiols with iron(III) nitrate on a bentonite carrier to give symmetrical disulfides takes place under very mild conditions [137].

An important method for the production of unsymmetrical disulfides is the thioalkylation of thiols with sulfenyl halides [138].

1.6.4. Production of Alkyl Polysulfides

Alkyl polysulfides are produced industrially by treating thiols with sulfur in the presence of bases (alkali-metal hydroxides or tertiary amines) [139]. Mixtures of various polysulfides are frequently formed in this reaction, so the isolation, purification, and characterization of defined compounds can be difficult. Higher molecular mass dialkyl trisulfides can be obtained in very good yields from the corresponding thiols and sulfur with magnesium oxide as the base at 30 – 100 °C [140]. The reaction of thiols with electrolytically formed $S^{2+}{}_x$ gives trisulfides in 53 – 74 % yields [141]. Alkyl polysulfides containing an average of five sulfur atoms can be prepared at room temperature in the presence of thioxanthates as catalysts [142].

The reaction of dihaloalkanes with alkali polysulfides gives polymeric polysulfides with the general formula $-[R-S_x-]_n$. These polysulfide rubbers (thioplastics) are widely used in industry because of their resistance toward chemicals and light and their impermeability toward gases (→ Rubber, 3. Synthetic, Chap. 5.3.; → Sealing Materials, Chap. 3.).

1.6.5. Uses of Alkyl Sulfides, Disulfides, and Polysulfides

The most important industrial application of aliphatic sulfides and disulfides is as intermediates in the production of pharmaceuticals, crop-protection agents, and a wide range of other substances [143]. Alkyl sulfide groups themselves are also present in the active components of many pharmaceuticals and crop-protection agents, especially insecticides [144]. *Dimethyl sulfide*, the industrially most important sulfide, is widely used in the form of the borane complex $(CH_3)_2S \cdot BH_3$ [*13292-87-0*] for the reduction of a variety of functional groups [145]. Dimethyl sulfide is also the starting material for production of the solvent dimethyl sulfoxide (DMSO; → Sulfones and Sulfoxides, Chap. 2.2.1.).

Organic disulfides have a variety of applications as well. L-Cystine [*56-89-3*] and lipoic acid [*1077-28-7*] are therapeutic agents for the liver. Holomycin and the pharmaceutically active component in garlic, di(1-propenyl) disulfide [146], exhibit antibacterial activity. Dialkyl disulfides with 2 – 8 carbon atoms per alkyl residue can be used as insecticides and acaricides (→ Acaricides, Chap. 3.5.), or to combat algae [133]. Higher molecular mass disulfides are used as additives in the plastics industry for chain transfer during polymerization, and as antioxidants (→ Oxidation, Chap. 4.4.3.). Di- and polysulfides are used as high-pressure additives for lubricating oils.

2. Aromatic Thiols, Sulfides, Disulfides, and Polysulfides

2.1. Physical and Chemical Properties

Aromatic thiols, Ar–SH, are sulfur analogs of phenols. This relationship is also manifested in many names, where the prefix thio is added to the trivial name of the corresponding phenol (e.g., thiosalicylic acid, thiocresol). According to IUPAC rules, aromatic thiols are supposed to be referred to as mercaptoarenes (e.g., mercaptoaniline) or arenethiols (e.g., 2-naphthalenethiol).

Aromatic thiols differ only slightly from alkanethiols with respect to acidity, salt formation, odor, and solubility. Many thiophenols are volatile in steam. Table 4 provides an overview of physical properties for several important arenethiols.

Unlike aliphatic thiols, arenethiols occur only to a very limited extent in natural materials. One reason for this may be the more facile oxidation of aromatic thiols, which are converted into disulfides simply on standing in air. The powerful nucleophilicity of arenethiols is exemplified primarily by substitution and addition reactions, most of which lead to thioethers. Such reactions correspond largely to those of aliphatic thiols (see Section 1.2.2). Unlike phenol derivatives, derivatives of aromatic thiols undergo a number of rearrangements. A review of the reactions of aromatic thiols can be found in [11].

Table 4. Physical data for several thiophenols

R	CAS registry no.	M_r	*bp*, °C/kPa	*mp*, °C	Flash point, °C

2-COOH	[*147-93-3*]	154.19		167	

2.2. Production of Aromatic Thiols

2.2.1. By Reduction

The reduction of sulfonyl chlorides, which are readily accessible from the corresponding aromatic systems by sulfochlorination, is one of the most important methods for producing arenethiols.

$$Ar-H + HO-SO_2Cl \xrightarrow{-H_2O} Ar-SO_2Cl \xrightarrow{Red.} Ar-SH$$

Many different reducing agents can be employed. The use of zinc or tin in dilute acid is still important in industry [147]. For example, *thiophenol* [148], *halothiophenols* [149], or *aromatic dithiols* [150] continue to be produced by this method. The resulting levels of ecologically harmful metal salts can be considerably reduced by the use of such catalysts as lead [151] or various harmless metal salts [152].

Sulfonyl chlorides can be hydrogenated directly in the presence of metal sulfide catalysts to the corresponding thiophenols at 150 – 275 °C and a pressure of 3 – 17 MPa [153]. This process is used to produce *p-thiocresol*. The preparation of *2,5-dichlorothiophenol* by pressurized hydrogenation of the corresponding sulfonyl chloride over a platinum catalyst is similar [154].

Another commonly used reducing agent is red phosphorus in the presence of hydrogen iodide in aqueous [155] or glacial acetic acid solution [156]. Two-step reduction of a sulfonyl chloride is also practiced on an industrial scale, as in the preparation of thiophenol. Depending on the reaction conditions, sodium arenesulfinates or disulfides are formed initially by sulfite reduction, and these are subsequently converted into thiophenols by pressurized hydrogenation in the presence of metal sulfides [157].

The reduction of aromatic sulfonic acids with triphenylphosphine in the presence of a reaction accelerator has also been described [158].

The tendency of aromatic thiols to undergo oxidation means that the actual products are often disulfides, so reduction of the latter and the corresponding polysulfides is frequently important. This indirect route to arenethiols often leads to better yields than the direct synthesis despite the additional reaction step. Many reducing agents are suitable for the reductive cleavage of disulfides. Pressurized hydrogenation in the presence of a catalyst is used in industry [159]. For halosubstituted compounds the preferred catalysts are Raney cobalt or palladium on charcoal [160]. Other reducing agents include metallic aluminum in liquid ammonia with inorganic halogen as the catalyst [161], zinc and acid in the presence of another metal [162], lithium aluminum hydride [163], hydrogen sulfide [164], and alkali-metal sulfides [165]. Functionalized aromatic disulfides are reduced selectively and under mild conditions using lithium (tri-*tert*-butoxy)aluminum hydride, where halogen, nitro, and carboxyl groups are spared from attack [166]. High yields of arenethiols are also obtained in the presence of a wide range of functional groups with a phosphine reagent bonded to a polymeric carrier [167]. For other reducing agents, particularly those used in the laboratory, see [2].

2.2.2. By Thiolation

A nucleophilic exchange between aromatically bonded halogen and the thiol group occurs under mild conditions only in the presence of other strongly electron withdrawing substituents, such as nitro or sulfonyl groups [168]. Either sodium hydrogensulfide or sodium disulfide is used as the thiolating agent. Poor yields and selectivities are often observed with sodium sulfide, particularly with weakly activated haloaromatics. Chloronitrobenzenes can be converted into the corresponding thiophenols either with retention [165, 169] or simultaneous reduction of the nitro group [170], depending on the reaction conditions.

Polychlorinated benzenes also react with sodium hydrogensulfide to give the corresponding thiophenols [171].

The thiolation of haloaromatics is often used in the industrial preparation of arenethiols. *Pentachlorothiophenol* is obtained

from hexachlorobenzene by treatment with sodium sulfide and sulfur in methanol, or with sodium hydrogensulfide [172, 173]. Various halothiophenols can be produced by a similar method in such polar solvents as DMF, sulfolane, dimethylsulfoxide (DMSO), and *N*-methylpyrrolidone [174]. Mercaptoanilines are formed from halonitrobenzenes with simultaneous reduction of the nitro group [175]. Aromatic dithiols can be obtained in a particularly pure state and high yield from polyhalogenated aromatics by reaction with hydrogen sulfide and sulfur in the presence of iron [176]. Sodium alkanethiolates can be used for the thiolation of nonactivated aryl halides. The aryl alkyl sulfide formed initially is converted into the desired aromatic thiol by acid hydrolysis [177]. Nucleophilic substitution of an aryl iodide with thiourea in the presence of transition metal complexes leads to *S*-arylisothiuronium salts, which can by hydrolyzed to arenethiols [178].

Another thiolating agent, one that is also suitable for the production of alkoxythiophenols, is disulfur dichloride. Disulfides are formed initially, and these are then reduced as described above (see Section 2.2.1). Various metal salts can serve as catalysts for this thiolation [179]. Similarly, monohalogenated benzenes can be converted into halothiols via polysulfides [180].

Other preparative methods applicable to arenethiols include the catalytic reaction of phenols with hydrogen sulfide in the gas phase [181] and reductive cleavage of aryl alkyl sulfides [182].

2.3. Uses of Aromatic Thiols

The most important industrial applications of arenethiols are as intermediates in the production of pharmaceuticals, agrochemicals [183], dyes, and pigments, and as chemicals for the electronics industry. Thiophenols are used in the rubber industry as polymerization regulators, plasticizers, and stabilizers [184], as well as for rubber reclamation. Aromatic dithiols and mercaptoanilines are used in the plastics industry as monomers and modifiers [185].

Thiophenolamides act as collagenase inhibitors, and can be used for treating arthritic conditions [186]. Thiophenolate-containing preparations can dissolve seals and coatings based on polysulfides [187].

Methyl and ethyl 2-mercaptobenzoates have been patented as scents [188]. Substituted mercaptoanilines are flotation agents for lead and zinc ores [189]. Polythiols can be used as optical materials in plastics [190], and for the production of lightweight reversible electrodes with high theoretical energy density [191]. The use of mercaptophenyl-substituted pyrrolinones as herbicides and growth regulators for crop-protection purposes has been described [192].

2.4. Production of Aryl Sulfides, Disulfides, and Polysulfides

The production processes for aromatic sulfides, disulfides, and polysulfides correspond largely to those for the related aliphatic compounds. Symmetrical aryl sulfides can be obtained by arylation of hydrogen sulfide or its salts with alkyl halides [193]. Similarly, unsymmetrical or mixed (aliphatic – aromatic) sulfides are formed from thiols or thiolates on treatment with alkyl or aryl halides [194]. The addition of thiols to multiple bonds [195] and the reaction of sulfenyl chlorides with arenes or phenols [196] also lead to unsymmetrical sulfides. Sulfides are formed as well in the cleavage of disulfides with phenols [197] or aromatic amines [198].

2.5. Uses of Aryl Sulfides, Disulfides, and Polysulfides

Aryl sulfides are used mainly as intermediates in the production of biologically active substances and dyes, and as monomers in the plastics industry.

Tetrasul and Mercaptodimethur are examples of commercial insecticides. Other aryl sulfides have been introduced as fungicides [199], herbicides [200], microbial growth inhibitors [201], acaricides and nematocides [202], miticides

[203], and gametocides [204]. Aryl thioethers are components of color developers in recording materials [205] and of the photosensitive elements in photocopiers and printers [206]. Certain monomeric aryl sulfides can be polymerized to materials with interesting optical properties, such as transparency or a high refractive index [207]. In the plastics industry arylthio compounds can be used as hardeners [208], antioxidants [209], or heat and light stabilizers [210]. Other aryl sulfides function as lubricating-agent additives [211], hair dyes [212], and flotation agents [213]. Aromatic sulfides are used in the pharmaceutcial sector for treating immunological diseases [214], skin diseases [215], and asthma [216], and also as muscle relaxants [217].

Aromatic disulfides have been patented as stabilizers for polycarbonate plastics [218], corrosion inhibitors in transport systems for crude petroleum and natural gas [219] and antioxidants for use in lubricating agents [220].

Aryl polysulfides in rubber act simultaneously as antioxidants and cross-linking agents [221].

Poly(*p*-arylenesulfides) are industrially important as thermoplastic polycondensates with good mechanical and thermal characteristics [222].

3. Heterocyclic Thiols, Sulfides, and Disulfides

3.1. Introduction

Heterocyclic thiols and their derivatives are widely distributed in nature. For example, the eggs of such marine invertebrates as sea urchins, starfish, and squid contain relatively high concentrations of mercaptohistidine and the corresponding methyl derivatives, known as "ovothiols" [223]. These compounds function as biological antioxidants in the fertilized eggs [224].

R^1	R^2	Ovothiol
H	H	A
CH_3	H	B
CH_3	CH_3	C

2-Methyl-3-furanthiol and its disulfide and *S*-methyl derivatives have all been identified as aroma components of cooked meat [225], and they have also been incorporated into synthetic flavorings [226]. 2-Methyl-3-furanthiol has been shown to be present in the aromas of roasted coffee [227] and canned tuna [228]. *S*-Substituted furans, thiophenes, thiazoles, and 3-thiazolines contribute to the odor of yeast extracts [229]. Heterocyclic sulfides occur in cytokinins of the bacteria *Escherichia coli* [230] and in the phallotoxins, toxic substances from the "death cup" mushroom *Amanita phalloides* [231].

3.2. Physical and Chemical Properties

Heterocyclic thiols are generally colorless or pale yellow solids with relatively faint characteristic odors. Table 5 provides an overview of the physical properties of several heterocyclic thiols.

Table 5. Physical data for selected heterocyclic thiols

Formula, name	CAS registry no.	M_r	*mp*, °C
Imidazole-2-thiol	[*872-35-5*]	100.14	228–231
2-Thiazoline-2-thiol	[*96-53-7*]	119.21	105–107
 [1*H*]-1,2,4-Triazole-3-thiol	[*3179-31-5*]	101.13	221–224
 5-Methyl-1,3,4-thiadiazole-2-thiol	[*29490-19-5*]	132.21	188–189
 1-Methyl-[1*H*]-tetrazole-5-thiol	[*13183-79-4*]	116.15	125–128
Pyridine-2-thiol	[*2637-34-5*]	111.17	128–130
 2-Mercaptonicotinic acid	[*38521-46-9*]	155.18	270 (decomp.)

Table 5. Continued.

Formula, name	CAS registry no.	M_r	*mp*, °C
Pyrimidine-2-thiol	[*1450-85-7*]	112.15	230 (decomp.)
 Benzothiazole-2-thiol	[*149-30-4*]	167.25	182
 6-Purinethiol hydrate	[*6112-76-1*]	170.19	>300
 2-Quinolinethiol	[*2637-37-8*]	161.23	174–176
 2-Mercapto-4[3*H*]-quinazolinone	[*13906-09-7*]	178.21	>300

Just like the corresponding aliphatic or aromatic compounds, heterocyclic thiols form salts with many metals, some of which have therapeutic applications (see Section 3.4).

Nitrogen-containing heterocyclic thiols are subject to the same tautomeric equilibrium between thiol and thione forms exhibited by the analogous oxygen species.

Spectroscopic studies [232] have shown that this equilibrium is displaced in the direction of the thione form. Reactions of heterocyclic thiols can take place from either the thiol or the thione form.

The mild oxidation of heterocyclic thiols leads to disulfides, just as with the corresponding aliphatic and aromatic systems. Catalytic oxidation of 2-mercapto-1,3-benzothiazol with atmospheric air is not practical, so the corresponding disulfide is prepared industrially by oxidation with sodium chlorate [233].

Stronger oxidizing agents like potassium permanganate or potassium peroxide transform heterocyclic thiols into sulfonic acids [234]. Treatment of 3-mercapto-1,2,4-triazole or 2-mercaptopyridinoimidazole with nitric acid leads to oxidative desulfurization [4].

However, a more widespread desulfurization method for heterocyclic thiols is the reductive approach, in which Raney nickel [235] or sodium borohydride [236] is usually the reagent of choice.

Oxidation of heterocyclic thiols with hypochlorite in the presence of excess amine results in the corresponding sulfenamides [237], and disulfides are subject to similar treatment [238].

Heterocyclic thiols or sulfides are easily transformed into amino or hydrazo derivatives by substitution [239].

Moreover, heterocyclic thiols are subject just like their aliphatic and aromatic counterparts to such transformations as etherification, esterification, or rearrangement.

3.3. Production

A wide variety of methods is available for the preparation of heterocyclic thiols. Thus, a thiol function can either be introduced by substitution into an existing heterocyclic system, or else the heterocycle itself may be constructed by cyclization of a sulfur-containing precursor.

3.3.1. Heterocyclic Thiols by Substitution

Generally speaking, heterocycles undergo substitution to thiols under substitution conditions similar to those applicable to activated benzene derivatives. One frequently applied method is the thiolation of a halo-substituted heterocycle, taking advantage of a wide range of thiolation reagents. Particularly suitable in this context are sodium or potassium hydrogensulfide [240] and thiourea [241]. Other possibilities include elemental sulfur [242], thiosulfate [243], alkali thiocyanates, and thiocarboxylic acid derivatives.

Heteroaromatic organomagnesium or organolithium compounds react with sulfur to give thiolates, hydrolysis of which leads to the corresponding thiols. This method permits the preparation of mercaptothiophenes in yields up to 70 % [244].

Similarly, the mercapto function can be introduced into *N*-protected 2-aminopyridines with dibenzylsulfide [245].

Just like aryl amines, heteroaromatic amines are subject to conversion by way of diazonium salts into the corresponding thiols [246].

Heterocycles bearing oxygen substituents can also be transformed into thiols. Suitable reagents include especially phosphorus pentasulfide [247], hydrogen sulfide [248], and the Lawesson reagent [249], just as in the case of alkanethiols (see Section 1.3.1).

Another reaction that has been used to prepare heteroaromatic thiols is the reduction of a sulfonic acid with iodine and triphenylphosphine [250].

3.3.2. Heterocyclic Thiols by Cyclization

Cyclocondensations with such sulfur-containing species as carbon disulfide, thiourea, or thiocyanates are especially important reactions for the synthesis of heterocyclic thiols.

Carbon Disulfide. 2-Mercapto-1,3-benzothiazoles are prepared on an industrial scale from anilines by cyclocondensation with carbon disulfide and sulfur. One reaction of this type exploited industrially, that of *o*-aminothiophenols, occurs even at low temperature [251].

o-Phenylenediamines react analogously to 2-mercaptobenzimidazoles, whereby potassium xanthogenate can be utilized in place of carbon disulfide if so desired [252].

1,2-Diaminoalkanes are transformed by carbon disulfide into 2-mercaptoimidazolines [253].

The cyclization of 2-aminobenzonitriles with carbon disulfide or potassium xanthogenate leads to mercapto-substituted quinazolines [254].

Cycloaddition of carbon disulfide to sodium azide produces the sodium salt of 5-mercapto-1,2,3,4-thiatriazole [255].

Thiourea. Condensation of carbonyl compounds with thiourea derivatives represents another important approach to the synthesis of heterocyclic thiols. Thus, cyclocondensation of α-hydroxyketones with thiourea results in 2-mercaptoimidazoles [256].

The analogous conversion of β-dicarbonyl compounds to 2-mercaptopyrimidines has been subject to especially widespread utilization [257].

The usual starting materials are β-diketones or β-ketoaldehydes along with the corresponding acetals and acetoacetic or malonic ester derivatives. The latter lead to thiobarbiturates, which are used as short-duration narcotics.

Thiourea reacts with two equivalents of an aldehyde and one equivalent of amine to provide mercapto-substituted 1,3,5-triazines [258].

Thiosemicarbazide undergoes a reaction similar to that of thiourea, and can be transformed with aliphatic or aromatic carboxylic acids into 3-mercapto-1,2,4-triazoles [259].

Thiocyanates. Potassium thiocyanate is a frequently employed reagent that lends itself to cyclization with aminocarbonyl compounds to 2-mercaptoimidazoles [260].

Isothiocyanates react with acylhydrazides in the presence of sodium alcoholate to give 3-mercapto-1,2,4-triazoles [261].

Other cyclization processes are described in [262].

3.3.3. Heterocyclic Sulfides and Disulfides

The synthetic methods applicable to heterocyclic sulfides and disulfides correspond largely to those for aliphatic and aromatic compounds (see Sections 1.6 and 2.4). Thus, heteroaromatic sulfides can be prepared just like their aromatic analogues by heteroarylation of such inorganic compounds as sodium sulfide or dichlorosulfane [263].

Unsymmetrical sulfides can be obtained from heteroaryl halides by treatment with sodium alkanethiolates or thiols [264]. Good yields are also observed in the palladium-catalyzed reaction of heteroaromatic halogen compounds with organotin sulfides [265].

Sulfenyl chlorides can be transformed into unsymmetrical sulfides with alkenes [266] or arenes [267].

4,5-Dinitroimidazoles are converted in high yield to thioethers through substitution of a nitro group [268].

For the preparation of heterocyclic disulfides see the methods described in Section 1.6.3.

3.4. Uses of Heterocyclic Thiols, Sulfides, and Disulfides

Numerous heterocyclic thiols and their sulfur derivatives have found application as intermediates in the synthesis of pharmaceuticals, crop-protection agents, and dyes. Additional applications are described in the sections that follow.

3.4.1. Pharmaceuticals

Many heterocyclic thiols and sulfides are among the active ingredients in commercially available drugs. Table 6 presents a few examples.

A wide range of such substances with antibiotic activity has been developed in the last few years, including systems with skeletons that differ from those of penicillin and cephalosporin. A review of the patent literature is incorporated into [274]. The description that follows provides a few examples of the broad spectrum of pharmaceutical activity associated with heterocyclic thiols and their derivatives.

Mercapto- (or alkylthio-) triazoles [275], imidazoles [276], imidazolines [277], and pyridines [278] inhibit the activity of dopamine-β-hydroxylases. 7-Thiosubstituted oxoquinolinecarboxylic acids [279], 2-amino-3-mercaptopyridines [280], and thiopyridine derivatives of 5-nitro-2-vinylfuran [281] display antibacterial activity, and the latter are also fungicides. Analgesic, antipyretic, and anti-inflammatory activity has been reported for certain thiopyridine derivatives [282], 2-mercaptoimidazoles [283], 3-amino--4-mercapto-6-methylpyridazines [284], and 3-mercaptotriazoles [285]. Mercapto-substituted imidazoles [286] and triazoles [287] have been patented as medicinal fungicides. 2-Mercaptobenzoxazoles can be used for both prophylaxis and treatment in the case of liver diseases [288]. Various heterocyclic thiols and sulfides inhibit the secretion of stomach acid, and can be utilized in ulcer treatment [289]. Mercaptopyrrolidine derivatives have been described as cough-prevention agents [290]. Mercaptopyrazolo-pyrimidines and -triazines represent potential schistosomicides [291]. Furanyl and pyranyl sulfides display immune-controlling characteristics [292]. Thio-substituted pyridazinones [293], imidazoles [294], and other heterocycles [295] display antiallergic and antiasthmatic activity. The gold salt of thioglucose shows in vitro antiviral activity toward the immune-deficiency virus HIV-1 [296].

Table 6. Heterocyclic thiols and sulfides used as pharmaceuticals

Thiol/Sulfide	Application	Ref.
2-Thiobarbituric acid 	anaesthetic narcotic hypnotic sedative	[269]
6-Thiopurine 	cytostatic agent antileukemic	[270]
2-Thiouracil 	thyreostatic	[271]
Cephalosporin 	antibiotic	[272]
2-Pyridinethiol-*N*-oxide Na salt Zn salt disulfide	antimycotic antiseborrhoeic fungicide, bactericide	[273]

3.4.2. Agricultural Chemicals

Heterocyclic thiols and sulfides are included as crop-protection agents in numerous commercial products. For example, several herbicides contain methylthio-1,3,5-triazines [297].

Other effective herbicides of considerable economic significance are the 3-methylthio-1,2,4-triazine-5(4*H*)-ones, which inhibit photosynthesis [298–300].

Mercapto-substituted pyrazoles [301] and imidazole-5-carboxylic acids [302] as well as 5-mercaptopyridine-3-carboxylic acid derivatives [303] have also been reported to show herbicidal activity.

A broad spectrum of activity has been reported in the extensive patent literature with respect to 1,2-pyridazinones containing thio substituents. For example, they can be used not only as pesticides in veterinary-medicine and crop-protection applications [304], but also as plant fungicides [305]. Other compounds effective as pesticides are derivatives of 1,2,5-thiadiazol-3-thiol [306] and heteroaryl vinyl sulfides [307]. 1-Oxopyridyl disulfides can be utilized as feed supplements in the raising of poultry [308].

3.4.3. Other Uses

Heterocyclic thiols and their salts are employed in the photographic sector as stabilizers and as protection against fogging. Patents have been issued in this context covering pyrazoles and triazoles [309], thiadiazoles [310], pyrrolidines [311], and benzimidazoles [312] with free mercapto groups, but also heterocyclic sulfides [313]. Other photographic auxiliaries contain mercaptopyridines [314]. 2-Mercaptobenzothiazole and its derivatives have been used to protect copper and copper alloys against corrosion. Corrosion-inhibiting properties have also been reported for 2-mercaptopyridines [315], 4,5-bismercapto-1,2-dithiol-3-one and its salts [316], and certain pyridine thioethers [317].

A few heterocyclic thiols are effective as stabilizers for microbicidal 3-isothiazolones [318].

Mercaptobenzimidazole and its derivatives have proven valuable in preventing the aging of rubber [319]. 2-Mercaptobenzothiazole is an important vulcanization catalyst in the rubber industry. Other compounds suggested for this purpose include mercapto-substituted triazine [320] and pyrimidine [321] derivatives. Derivatives of 2,5-dimercaptothiadiazole [322] as well as aminobis- and aminotris(alkylthio)triazines have been suggested as stabilizers for natural and synthetic rubber [323].

Heterocyclic anthraquinone thioethers have been described as dyes for liquid crystals [324]. Thioethers [325] and disulfides [326] of furans and thiophenes are cited in patent literature as flavoring food additives.

2-Mercaptobenzothiazole plays a role in analysis as a reagent for cadmium as well as for the determination of copper, lead, bismuth, silver, mercury, thallium, gold, platinum, and iridium. 4-Amino-3-hydrazino-5-mercapto-1,2,4-triazole (Purpald, Aldrich) is a reagent specific for aldehydes [327]. Other analytical applications of heterocyclic thiols and sulfides are discussed in [328].

Cosmetic applications include the use of 2-mercaptopyridine to prevent the formation of melanin in the skin [329], and of certain heterocyclic thiols as active ingredients in deodorants [330].

4. Toxicology [331–335]

Most thiols are classed as moderately toxic compounds. Since many thiols and sulfides are readily detectable on the basis of their odors at levels far below the danger point, these odors serve to provide a warning. Exceptions include 2,4,4-trimethyl-2-pentanethiol (*tert*-octanethiol), cyclohexanethiol, and thiophenol, which are significantly more toxic than short-chain thiols. Toxicity decreases with longer-chain thiols.

The SH group plays a significant role in biological metabolism (e.g., in metabolite transfer), and for this reason thiols may exhibit either inhibitory or accelerating effects on metabolic processes. A comprehensive treatment of the metabolic, biochemical, and toxicological aspects of xenobiotics containing thiol or sulfide functions is presented in [333].

The discussion that follows constitutes a brief description of the toxic properties of a few representative thiols, sulfides, and disulfides.

Methanethiol (Methyl Mercaptan). The greatest risk with respect to this compound involves inhalation, and the corresponding toxic properties are comparable to those of hydrogen sulfide. Low concentrations lead to irritation of the eyes and mucous membranes, headache, nausea, and vomiting. Irritation of the respiratory tract may lead to edema in the lungs. Higher concentrations result in increased blood pressure and pulse rate, coma, severe anemia, and death. Inflammation of the skin (dermatitis) is observed to accompany chronic exposure to low concentrations. MAK: 0.5 ppm (1 mg/m^3); TLV: 0.5 ppm.

Ethanethiol (ethyl mercaptan) has shown moderately toxic effects in animal experiments in conjunction with inhalation, oral ingestion, or intraperitoneal application. Low concentrations (4 ppm) lead in the case of humans to irritation of the skin and eyes, headache, and nausea, and respiratory rate also decreases at an exposure level of 50 ppm. Extended exposure to 4 ppm of ethanethiol results in a decrease in odor sensitivity. MAK: 0.5 ppm (1 mg/m^3); TLV: 0.5 ppm.

n-Propanethiol (propyl mercaptan) has been shown in animal studies to display little toxicity upon oral administration, and it is essentially nontoxic with respect to inhalation. Its effect as an irritant to mammalian skin and eyes is also low. On the other hand, human subjects residing adjacent to a field treated with the pesticide Ethioprop (Mocap) displayed health impairments that persisted for as long as six weeks as a result of the release of propanethiol. The symptoms described included headache, sore throat, diarrhea, and irritation of the eyes, as well as hay fever and asthma attacks [336].

Butanethiols. The inhalation of 50–500 ppm of *n-butanethiol* over a period of one hour led in the case of seven human subjects to modest to severe signs of poisoning, including such symptoms as weakness, increased respiratory rate, pain in the neck, nausea, and depression of the central nervous system (diminished reaction capability). MAK: 0.5 ppm (1.5 mg/m^3); TLV: 0.5 ppm. *tert-Butanethiol* has been shown in animal experiments to be somewhat less toxic than the straight-chain isomer. Both butyl thiols are eye irritants. MAK and TLV values for these compounds have not yet been established.

Cyclohexanethiol causes eye irritation and severe skin damage. Animal experiments (rats) involving oral ingestion have revealed a low LD_{50} of 558 mg/kg.

tert-Octanethiol has been found in animal studies to be toxic by oral ingestion, inhalation, or intraperitoneal application, and moderately toxic upon resorption through the skin. The lowest lethal dose (intraperitoneal) is reported for rats at 11 mg/kg.

Dodecanethiols. The toxicity of *n-dodecanethiol* is low. Chronic exposure has been observed to produce skin irritation and sensitization. In the case of *tert-dodecanethiol* (isomeric mixture) animal studies based on oral administration produced a very low LD_{50} of 309 mg/kg. Skin and eye irritation was also noted.

Thiophenol (phenyl mercaptan) has a severe irritating effect on the skin and eyes, and can lead to acute dermatitis. Headache and dizziness may accompany working with the compound. Animal studies have shown that chronic inhalation of high concentrations may cause damage to the liver, lungs, and kidneys. No MAK value has yet been established; TLV: 0.5 ppm. Thiophenol as well as *o-* and *p-aminothiophenols* cause the transformation of oxyhemoglobin into methemoglobin in human erythrocytes [337]. *p-Chlorothiophenol* and *pentachlorothiophenol* cause severe eye irritation, and the former may be carcinogenic.

Alkyl sulfides are generally described as moderately toxic compounds that may lead to hemolytic anemia and allergic dermatitis. *Dimethyl sulfide* is responsible for skin irritation and severe eye irritation. Certain diaryl sulfides [e.g., 2,2′-thiobis(4,6-dichlorophenol) and 4,4′-thiodianiline] are suspected of being carcinogenic.

2-Mercaptobenzothiazole has a sensitizing effect, and with chronic exposure (e.g., through

the use of rubber gloves) it may induce skin reactions [338]. *2-Mercapto-1-methylimidazole* displays teratogenic effects in humans, and it is suspected of being a carcinogen. *6-Mercaptopurine derivatives* influence cell division, and have been employed as cytostatic agents. They have been found to be teratogenic in animal studies. *Methylthio-substituted triazines*, which are used as herbicides, are only slightly toxic. The corresponding LD_{50} or LC_{50} values derived from animal studies are above the level of 1000 mg/kg [339]. Similar values have been established for a methylthiotriazinone that is the active ingredient in the herbicide Sencor [340].

The professional literature should be consulted regarding the diverse toxic side effects of the many pharmacologically active heterocyclic thiols and sulfides.

1. Introduction

The simple derivatives of thiophene are stable liquids closely resembling the corresponding benzene derivatives in boiling points and even in odor. Thiophene and its simple alkyl derivatives occur in neutral coal tar distillates, which led to the discovery of thiophene by VICTOR MEYER in 1882. Prior to the discovery a classical test for benzene was the development of a blue color on heating with isatin and concentrated sulfuric acid. During a lecture demonstration by MEYER in 1882 this test failed. Upon investigation it became apparent that the lecture assistant had used benzene made by decarboxylation of benzenecarboxylic acid rather than commercial benzene containing the impurity which was discovered to be a new ring system. The new system was subsequently named thiophene from *theion*, the Greek word for sulfur, and *phaino*, another Greek word meaning shining. The word *phaino* had already been used in naming phenol because of its occurrence in coal tar, a byproduct of the manufacture of gas used in lighting in the 19th century.

Thiophene compounds occur rarely in plants and do not play any part in animal metabolism. However, they have found extensive use in pharmaceuticals and agrochemicals and play a minor role in commerce as constituents of reactive dyes, conductive polymers, ligands for catalyst systems, and in flavor and fragrances. The extensive literature on thiophenes is indicative of the commercial and research interest in this five-membered sulfur heterocycle. Some hundreds of patents appear each year, many using thiophene derivatives as alternatives to benzenoid products, in many cases the thiophene containing molecule exhibiting higher activity than the benzene analogue.

The process to manufacture thiophene (and its homologues) by the gas-phase interaction of aliphatic compounds with sulfur derivatives is capable of unlimited expansion, but thiophene production remains a fine-chemical business in the scale of around 1000 t/a.

This article concentrates on the products of current commerce. Chapter 6. Uses covers over 90 % of the present uses; the remainder consists of minor products, mainly pharmaceuticals, together with several which are still in the very early stages of development.

2. Physical and Chemical Properties

The physical characteristics of thiophene (thiofuran) are closer to benzene than any other five-membered heterocyclic. This enables thiophene to replace a benzenoid moiety in the whole spectrum of aromatic chemicals [1] and, as illustrated in Chapter Uses, sometimes to introduce worthwhile advantages over the analogous benzenoid compounds.

Some physical and physicochemical properties of thiophene are listed below:

The numbering of the thiophene ring is orthodox:

Nomenclature can be summarized as

2-Thenyl

2-Thienyl

2-Theonyl

The usefulness of thiophene and its derivatives lies in their reactivity to substitution by electrophilic reagents. Thiophene is a π-electron-rich aromatic with six π-electron distributed over five ring atoms (Fig. 1); this facilitates the attack by electrophiles at ring carbons. The literature illustrates the ease of electrophilic substitution in the 2- and 5-positions (Fig. 2). As in other five-membered heterocyclics, the S atom of the thiophene ring plays its part in the formation of cationic reaction intermediates. Thus, the reactivity of thiophene is more akin to that of phenol and aniline than to the comparatively unreactive benzene ring.

Figure 1. Delocalization of -electrons in the thiophene ring

With the 2-position occupied by an *o*/*p* -directing group, a second group is substituted in the 5-position of the thiophene ring. With a *m*-directing group in the 2-position a second group is substituted in the 4-position.

As can be seen from Figure 2, many 2-substituted derivatives can be produced by orthodox and comparatively mild organic chemical reactions. However, amino, hydroxyl, and thiol substituted thiophenes are unstable unless an electron attracting group is also attached to the thiophene ring, e.g., reduction of 2-nitrothiophene gives 2-aminothiophene which decomposes very rapidly in air but is stable in an inert atmosphere or as a salt.

While 2-substitution is practically 100 %, single-percentage amounts of the 3-isomer may be formed. Routes and reaction conditions to limit this effect need to be optimized.

The order of reactivity toward electrophilic substitution is:

Pyrrole >> thiophene > furan >> benzene e.g., bromination of thiophene is 1.25×10^7 faster than that of benzene; chlorination 1.7×10^7 faster.

Thiophene and alkylthiophenes do not react with nucleophilic reagents by either substitution or addition. Similar to other five-membered heterocycles they only react with strong bases and then by deprotonation of the 2-position carbon. Alkyllithium bases such as butyllithium give a synthetically useful thienyllithium. Because the factors which determine the deprotonation are different to those affecting electrophilic substitution such reactions can be used to produce isomeric products.

Figure 2. Electrophilic substitution reactions of thiophene

Given the chemistry and availability of commercial thiophene derivatives most 2-substituted thiophenes are obtained by electrophilic substitution of thiophene and subsequent modification of the substituent, whilst 3-substituted thiophenes are made by modification of the two commercially available 3-thiophenes, namely 3-methylthiophene and 3-bromothiophene.

Irradiation causes thiophene to react with H_2O [2]:

Heating thiophene does not yield C_2H_2, but bithenyl [2]:

3. Resources and Raw Materials

Thiophene occurs in the light hydrocarbon fraction distilled from coal tar. The proportion of thiophene depends on the type of coal, the temperature of carbonization, and the type of retort. Typical quantities in a tar-derived benzol stream are 0.4 – 1.4 wt % [3].

Traditionally, thiophene is removed from coal tar benzol by washing with H_2SO_4, because the thiophene is more easily sulfonated than the aromatic materials present in the mixture, more rarely thiophene can be extracted by solvent extraction.

The very large volumes of light hydrocarbons produced from coal carbonization plants represent a considerable quantity of associated thiophene, but the quality demands of the principal markets for thiophene require a purity which cannot be obtained economically from coal tar due to the difficulty in separating it from benzene as demonstrated by Meyer.

Commercialization of thiophene for the fine chemicals intermediate market required a synthetic high-purity production method. This was initiated in the 1960s in the United States by Pennsalt/Pennwalt, now Arkema. Midland-Yorkshire Tar Distillers/Synthetic Chemicals, now Degussa, first produced synthetic thiophene on a commercial scale in Europe in 1970.

A key factor in the commercial production of pure thiophene and its homologues is the specificity and cleanliness of the processes used, because often the impurities and byproducts of the reaction are difficult to separate from the main product. Vapor phase (VP) cyclization methods are the processes of choice.

The original VP process, using furan and H_2S as the sulfur source [4], is no longer preferred. Degussa operates its own VP process at its site in Knottingley, UK [5], using CS_2 plus a selected C_4 skeleton. A similar VP process is patented by Arkema [6].

Other, non-VP processes may be described as laboratory or semiscale methods and include: (**1**) syntheses from C_4 unsaturates, using H_2S, Li_2S, SO_2, and S as sulfur sources; (**2**) succinic salts and γ-diketones with, e.g., P_4S_7 or P_4S_{10}; (**3**) thiodiacetates and 1,2-dicarbonyl compounds

Figure 3. Thiophene production
a) Raw materials tank farm; b) Mixer/flow control; c) Condenser; d) Multitube, fixed-bed VP (vapor phase) reactor

(the Hinsberg synthesis); (**4**) mercaptoacetates and 1,3-dicarbonyl compounds. Such processes often result in very complex reaction products and large amounts of waste making them unsuitable for large-scale production.

4. Production

Since the current international market for thiophene is <1000 t/a, the type of VP installation required for its manufacture is much smaller than a typical petrochemical unit. However, the process is capable of expansion to match any required demand.

Tight operating temperatures of 500–530 °C, catalyst performance, and regeneration plus overall control, particularly with respect to environmental requirements, are key factors in the successful operation of such a unit (Fig. 3).

A typical feedstock portfolio is shown in Figure 4.

The advent of a range of commercially available alkylthiophenes, including those substituted in the difficult 3-, (4-) position, resulted in an alternative raw material to synthesize a range of 3-, (4-) side-chain thiophenes, other than from, e.g., 3-bromothiophene [7].

5. Specifications, Transportation, Health and Safety

Data for thiophene, together with its 2-methyl, 3-methyl, 2-acetyl, and 2-bromo derivatives are given in Table 1.

Figure 4. Feedstocks for thiophene and its derivatives

6. Uses

Successful commercial derivatization is governed by the physical and chemical characteristics of the basic thiophene nucleus outlined in Chapter 2.

By far the greatest volume of simple thiophenes are produced by means of VP cyclizations (see Chapter 4). Derivatives of these homologues account for most of this business, in areas as diverse as pharmaceuticals, veterinary drugs, agrochemicals, to dyes, photography, and polymers.

6.1. Acylated Thiophenes

The Friedel-Crafts acylation of thiophene is a much used reaction producing more than 50% of the world market of thiophene derivatives. Use of standard Friedel-Crafts catalysts such as anhydrous aluminum chloride directly with thiophene gives rise to intractable tars and very low yields and as a consequence the catalyst has to be added gradually to the mixture of thiophene and acylating agent. Acylation with acid anhydrides can be catalyzed by strong acids such as phosphoric acid and this method can be used to manufacture 2-acetylthiophene. Vilsmeier formylation proceeds readily to make thiophene-2-aldehyde.

Thiophene 2-aldehyde (T2A), C_5H_4OS M_r 112.15, *bp* 198 °C, is prepared as shown in Figure 2 [8]. It was the first oxygenated derivative to reach a market of several hundred tons per year in the 1970s.

It was originally used to produce a range of antihistamines, including methapyrilene (**1**) [9], methaphenilene (**2**) [10], and thenalidine (**3**) [11]. However, this usage has practically disappeared.

1

2

3

The anthelmintic pyrantel (**4**) [12] (→ Anthelmintics) is an important outlet for T2A, enhanced by new formulations and the development of the medicinal use of pyrantel beyond the original veterinary market.

4

An important T2A derivative is the antihypertensive eprosartan (2-thiophenepropionic acid methyl ester) (**5**) [13], which acts as a selective angiotensin II receptor antagonist.

5

Other pharmaceuticals containing T2A are azosemide (**6**) [14] a diuretic, and teniposide (**7**) [15] an antineoplastic.

6

7

2-Acetylthiophene (2AT) C_6H_6OS, *bp* 214 °C, *mp* 9 °C, is prepared as shown in Figure 2. 2AT is used as an important precursor to thiophene-2-acetic acid (T2AA) or its acid chloride (Cl) and thiophene-2-carboxylic acid (T2CA) (Cl). It is important that the process used to synthesize 2AT yields the lowest amount of 3-acetylthiophene isomer.

Thiophene 2-carboxylic acid, T2CA, $C_5H_4O_2S$, M_r 128.15, *bp* 260 °C, *mp* −130 °C, is prepared via oxidation of 2-acetylthiophene (see Fig. 2) using hypochlorite, because oxidation of alkylthiophenes leads to general breakdown of the thiophene ring.

The sodium salt of T2CA is used to treat influenza (trophires) [16]. Other salts, e.g., the Li salt, have minor medicinal uses and the free acid is a mucolytic. A US Patent [17] describes the use of the Na salt as a lubricating oil thickener.

Suprofen (**8**) [18], a nonsteroidal anti-inflammatory (NSAI), and tienilic acid (ticrynafen) (**9**) [19], a potent diuretic, were both very large prospective markets for T2CA or its acid chloride, but were almost completely withdrawn in the 1980s. Sanofi Aventis' NSAI tiaprofenic acid (**10**) was comparatively successful in this market, but although it is still marketed it has subsequently been superceded by alternative products.

8

9

10

The 5-nitro derivative of T2CA is used to produce nifurzide, an intestinal antibacterial.

Pfizer's anti-inflammatory tenidap (**11**) [20] is a developing drug which uses the acid chloride of T2CA as the starting intermediate.

11

Thiophene 2-acetic acid, T2AA, $C_6H_6O_2S$, M_r 142.18. The use of 7-aminocephalosporanic acid (7ACA), following the classical work by the National Research and Development Council in the 1950s [21] to produce a family of semisynthetic cephalosporins, resulted in important first-generation antibiotics (→ Antibiotics, Chap. 3.1.4). Cephaloridine (**12**) [22] and cephalothin [23] were the major products licensed from this work. The second-generation cephalosporin cefoxitin (**13**) [24] came a few years later.

T2AA, or its acid chloride, is used to form the 7-side-chain of these antibiotics. Many processes have been designed to synthesize T2AA (Cl), including chloromethylation of thiophene until the late 1980s in the United States, and starting from T2A in the FAMSO process in Japan.

However, these processes are now superseded, and the oxidation and reduction of 2-acetylthiophene is now the process of choice.

12

13

Ketotifen fumarate (**14**) [25] is an antiasthma drug (→ Antiallergic Agents, Chap. 2.1.7), which is thought to possess prophylactic properties, and this market is growing.

14

Pizotyline (**15**) [26], an antimigraine agent, is synthesized from T2AA (Cl).

15

Thiophene aldehydes and ketones undergo all the carbonyl reactions of benzenoid aldehydes and ketones. For example 2-propionoylthiophene undergoes Wolff- Kishner reduction to prepare 2-propylthiophene used in the antiparkinson and antiabuse drug adrogolide [27]. Acetylthiophene will undergo a classical Mannich reaction to form the important intermediate 3-(dimethylamino)-1-(2-thienyl)-1-propanone for the antidepressant and antiurinary incontinence drug duloxetine (**16**) [28]. Similar chemistry is used to convert 2AT to the sedative indiplon [29]. Thiophene-2-aldehyde reacts with nitromethane to form the 2-(2-nitroethenyl)thiophene used in the manufacture of the ACE inhibitor temocapril (**17**) [30].

16

17

Thiophene Dicarboxylic Acids. Adipic acid, or its dichlorinated derivative, provides a means of forming thiophene 2,5-dicarboxylic acid [31]. Thiophene aldehydes and other substituents exhibit pronounced fluorescence [32]:

More complicated thiophene polybenzoxazoles are used as optical brighteners, and may be synthesized via the 2,5-carboxylic acid groups.

6.2. Halogenated Thiophenes

The halothiophenes are used widely in the synthesis of thiophene derivatives as intermediates for the preparation of thienyllithium or thienyl Grignard reagents.

2-Bromothiophene (2BT), C_4H_3Br, M_r78.17, bp 153.5 °C, is easily produced to a good purity (see Fig. 2) [33].

Tipepidine (**18**) [34], is an example of an antitussive produced from 2BT via a Grignard reaction. Other examples include tiotropium bromide, an antiasthma drug [35], tiquizium bromide [36], tiemonium iodide [37], and timepidium bromide [38], all antispasmodic drugs.

18

Reaction of either 2-thienyllithium or thiophene-2-magnesium Grignard with ethylene oxide generates thiophene-2-ethanol an important intermediate in the manufacture of ticlopidine (**19**) [39] and clopidogrel (**20**). Both are potent pharmaceuticals, used to prevent blood platelet aggregation in the treatment of strokes.

19

20

Reaction of 2-thienyllithium with sulfur generates the 2-mercaptothiophene, which, whilst not stable, can be used in situ and this is employed to make the antiglaucoma drug dorzolamide [40] and antineoplactic drug batismastat [41].

Dichlorination and acetylation is utilized in the synthesis of the antiglaucoma drug brinzolamide (**21**) [42]

21

3-Bromothiophene (3BT), C_4H_3Br, *bp* 160 °C. In order to obtain 3-(4-)substituted thiophenes, more elaborate chemistry is required than straightforward electrophilic substitution. Successive bromination to 2,3,5-tribromothiophene can be followed by removal of the 2- and 5-Br atoms (see Fig. 2), but, a newer, simpler process has been patented [43] which gives 3-bromothiophene essentially free of 2-Br isomer.

3-Bromothiophene may be used to produce thiophene 3-malonic acid (TMA), the side-chain intermediate for the production of ticarcillin and temocillin from 6-aminopenicillinic acid (6APA). Timentin (**22**) is a powerful antibiotic, produced from ticarcillin plus clavulanic acid [44]. An alternative route to TMA is via 3-methylthiophene (see Section 6.3).

22

3-Thienyllithium derived from 3-bromothiophene is used in the preparation of the vasodilator cetiedil [45].

6.3. Alkylthiophenes

Alkylation of thiophene occurs readily but is not of any utility given the poor selectivity and as a consequence resinification of reaction mixtures. Generally the methylthiophenes are available by VP cyclization (see Fig. 4) or by modification of bromo or acyl groups on the thiophene ring.

The presence of an alkyl group on the thiophene ring does not hinder the reactions outlined elsewhere but also allows derivatization via the halogenation of the alkyl group.

2-Methylthiophene (2MT), C_5H_6S, *bp* 112.5 °C, *mp* 63.4 °C, is commercially produced to 98 wt % purity by VP cyclization (see Fig. 4).

It is a feasible raw material for the production of several of the important 2-substituted thiophenes. It may be used to manufacture 2-chloromethylthiophene (2-thenyl chloride), but this and further syntheses must be completed in situ, because of its instability.

3-Methylthiophene (3MT), *bp* 115 °C, is commercially produced by an analogous process to 2MT, and to the same purity.

Thenyldiamine (**23**) [46], an antihistamine, has been produced since the late 1940s. The synthesis requires a source of 3MT to prepare the 3-thenylbromide precursor.

23

Morantel (**24**) [47] is a potent anthelmintic, differing from pyrantel (→ Anthelmintics) only in the additional 3-methyl group on the thiophene ring. Production of morantel is an important market for 3MT.

24

As stated above, the semisynthetic penicillins ticarcillin (**25**) [48] and timentin possess a 3-thienyl side-chain; 3MT, via free radical bromination of the methyl side-chain, is an alternative precursor to TMA.

The antifungal tioconazole (**26**) [49] is synthesized from 2-chloro-3-methylthiophene.

25

26

Cetiedil (**27**) [50] is a peripheral vasodilator which incorporates a thiophene ring in the 3-position; 3MT provides a means of synthesis.

27

Tiagabine (**28**) is an antiepileptic [51] which incorporates two 3-methylthiophene rings that are linked to each other via organometallic intermediates.

28

There has been much growing interest in conducting polymers based on polythiophenes and poly-3-alkylthiophenes which has been extensively reported [48, 52]. In order to produce a workable polythiophene, a fairly long side-chain

may be introduced at the 3-position of the thiophene ring. Choice of the structure of this side-chain is a compromise between the workability and the maintenance of required conductivity. The chain length of the attached n-alkyl group generally lies between C_4 and C_{12}. A commercial polythiophene has been promoted based on polymerization of 3,4-ethylenedioxythiophene (PDOT) manufactured by the Hinsberg synthesis – two consecutive aldol condensations between diethyl oxalate and diethyl thiodiacetate. Polymerization is via the 2- and 5-positions.

Removal of the 3-Br atom and replacement by an alkyl group is a means of obtaining the desired monomer.

R = $C_5 - C_{10}$ alkyl
Conducting polythiophene

6.4. Amino- and Hydroxylthiophene Derivatives

The commercial availability of a range of thiophenes substituted with an amino group, together with other ring substituents, is based on a modification of the Gewald reaction [53], for 2-NH_2 derivatives. An example of a 2-aminothiophene of synthetic utility is the fungicide sillthiopham [54] made from 2-amino-3,4-dimethyl-3-thiophenecarboxylic acid ester via a Gewald synthesis. Substitution of an amino group in the 3-position requires custom-designed chemistry [55, 56]. Aminothiophenes containing electron attracting groups such as ester groups can be easily diazotized and coupled.

Methyl 3-amino-4-methylthiophene 2-carboxylate $C_7H_{10}NO_2S$. The 3-amino group is used to attach a side-chain to the thiophene ring for manufacture of the local anesthetic carticaine (**29**) [57].

29

Methyl 3-aminothiophene 2-carboxylate $C_6H_7NO_2S$. This derivative is used to produce a sulfonylurea post-emergent herbicide, Harmony (M6316 DuPont) (**30**), which has extremely rapid biodegradability [58]. This characteristic, together with the very low dose requirements, are important environmental safeguards.

The NSAI tenoxicam (**31**) [59] is one of a range of oxicams which contain a thiophene moiety and may be synthesized from this aminothiophene carboxylate. Chlorination of tenoxicam yields lornoxicam (**32**) [60] a NSAI with higher activity.

30

31

32

Similar chemistry —cyclization to amino- and hydroxythiophenes —is used to manufacture the antihypertensive sitaxsentan [61], sedative brotizolam [62], peristaltic stimulant pumosetrag [63] and rice herbicide thenychlor [64].

The antipsychotic drug olanzapine (**33**) is made from the 5-methyl-2-aminothiophene-3-carbonitrile

Table 2. Toxicological data for thiophene and derivatives

	Thiophene	2-Methylthiophene	3-Methylthiophene	2-Acetylthiophene	2-Bromothiophene
Acute Toxicity					
Oral LD_{50}	1400 mg/kg (rat)	3200 mg/kg (mouse)	2300 mg/kg (rat)	50 mg/kg (mouse)	200 – 250 mg/kg (rat)
Dermal LD_{50}	830 mg/kg (rabbit)	no data	2000 mg/kg (guinea pig)	370 mg/kg (rat)	134 mg/kg (rat)
Inhalation LC_{50}	9500 mg/kg (mouse)	no data	10 g/m3, 2 h (rat)	1460 mg/m3, 1 h (rat)	1.04 mg/L, 4 h (rat)
Irritation					
Skin	yes	expected	yes	not reported	yes
Eye	yes	expected	yes	predicted	yes
Skin sensitization	no data	no data	not found in tests	no data	no data
Occupational exposure limits	none specified	none specified	none specified	2 ppm (provisional)	1 ppm (provisional)
Ecotoxicity	possibly only slight harm to aquatic organisms	possibly only slight harm to aquatic organisms	possible only slight harm to aquatic organisms	harmful to aquatic organisms	expected only slight harm to aquatic organisms
Persistence	expect ultimate biodegradability	expect ultimate biodegradability	expect ultimate biodegradability	expect ultimate biodegradability	expect very slow biodegradability
Stability					
Materials to avoid	strong oxidizers	strong oxidizers	strong oxidizers	strong oxidizers	strong oxidizers
Conditions	stable under normal conditions	stable under normal conditions	stable under normal conditions	stable under normal conditions	slow decomposition unless cool/dark
Combustion products	toxic oxides of S+CO, CO_2	toxic oxides of S+CO, CO_2	toxic oxides of S+CO, CO_2	toxic oxides of S+CO, CO_2	HBr during storage (prolonged), CO, CO_2

33

6.5. Reduced Thiophenes

The thiophene ring is not normally reduced by hydride reagents and the tetrahydrothiophene ring is normally made via other routes such as cyclization or vapor phase routes. Treatment of thiophenes with Raney nickel can give rise to desulfuration of the thiophene.

Tetrahydrothiophene (THT), C_4H_8S, M_r 88.18, *bp* 121.1 °C, *mp* −96 °C, is easily confused with thiophene itself, particularly since it may also be called thiophane. THT was certainly produced in commercial quantities before thiophene, and it remains a commercial product.

Tetrahydrothiophene is not manufactured from thiophene, but by VP replacement of the oxygen atom in tetrahydrofuran by sulfur from H_2S. The plant and catalyst used are very similar to a thiophene unit. However, THT is used for its very strong odor, either on its own or, more commonly, within a cocktail, e.g., alkylsulfides, as a powerful gas odorant. The saturation of comparatively sweet-smelling thiophene thus produces vastly different odor characteristics.

The herbicide dimethamid-P [65] is made via the tetrahydro-3-imino-2,4-dimethylthiophene which is made by cyclization of a thioester with methacrylate.

6.6. Miscellaneous Thiophenes

The use of *thiophene* mixed with other constituents to produce a denaturant has been developed [66]. Since thiophene does not occur in fermented alcohol, the addition of a marker containing thiophene facilitates the identification of alcohol denatured in this way. The thiophene is very difficult to remove.

Uses of thiophene itself have otherwise been restricted to analytical techniques, where a standard mass of sulfur is required for measurement control. Thiophene may also be used for quantitative deactivation of cracker catalysts.

The amino group, when in the 2-position of a substituted thiophene derivative, may be diazotized to a range of monoazo disperse dyes [67]. Coupling occurs with a pyrazolone or, e.g., phenol, and colors toward the yellow/green part of the spectrum are produced.

Substituted thiophene molecules are found in various components of animal and vegetable flavorings. The combination of H_2S with unsaturated aldehydes may be the source of such thiophene derivatives in, e.g., cooked beef, pork liver, onion, and coffee [68, 69].

As well as the fused ring structures illustrated above, which are valuable commercial products, others are worth mentioning, because of their potential markets.

Many methods are available to synthesize fused thieno rings to a nitrogen heterocyclic [70, 71].

There are several benzothiophenes used as pharmaceuticals including the anticancer drug *raloxifene* (**34**), these are generally manufactured by the cyclization of a thiophenol derivative.

34

7. Toxicology

Toxicological data for thiophene and its derivatives are given in Table 2.

1. Introduction

Thiourea is a chemically interesting compound, which has three functional groups: amino, imino, and thiol. This results from tautomerism between thiourea and isothiourea:

Because of this polyfunctionality and also because of its complex-forming properties, thiourea has been widely used for more than 30 years [1–5]. Its most important uses are as a starting material for nitrogen- and sulfur- containing heterocycles and formamidinesulfinic acid (thiourea dioxide), as a reaction partner for aldehydes, and as a component of addition compounds and complexes.

Thiourea derivatives are thermally stable, mostly crystalline compounds. They can be produced in good yields from readily available starting materials by simple syntheses. This class of compounds, described in detail in several review articles [6–11], has gained importance in the pharmaceutical sector, in plant protection, in various technical applications, and in the synthesis of heterocycles.

2. Thiourea

2.1. Physical Properties

Thiourea [*62-56-6*], 2-thiourea, CH_4N_2S, M_r76.12, d_4^{20} 1.405, is a white, odorless solid, and crystallizes in a rhombic bipyramidal structure with four molecules per unit cell. It is the only known molecular crystal which is ferroelectric within a certain temperature range. Space group $D_2^{16}{}_h - P_{\mathrm{nma}}$.

Thiourea is soluble in protic and aprotic polar solvents (Table 1) and insoluble in nonpolar ones.

Table 1. Solubility of thiourea

In H_2O						
Temperature, °C	0	20	40	60	80	100
Solubility, g/100 g	4.9	13.7	30.7	70.9	138	233
In MeOH						
Temperature, °C			25	40.7	53.7	61.9
Solubility, g/100 g			11.9	16.4	22	24.6
In EtOH						
Temperature, °C		20	31.9	45	58	64.7
Solubility, g/100 g		3.6	4.7	6.3	8.5	9.8

Thiourea has no sharp melting point, as it rearranges relatively rapidly to ammonium rhodanide (NH_4SCN) from 135 °C. On rapid heating, a melting point of 180 °C has been determined. The heat of combustion at constant vol-

10.1002/14356007.a26_803

ume is 1482.2 kJ/mol (19.47 kJ/g), and at constant pressure 1485.6 kJ/mol (19.52 kJ/g).

2.2. Chemical Properties

Although it is known in only one form, thiourea can also react as the tautomeric iminothiol (see Section 3.2). Salts such as $(NH_2)_2CS \cdot HNO_3$ or $(NH_2)_2CS \cdot H_2SO_4$ are formed with strong acids [3]. Addition compounds and complexes can be synthesized with metal oxides or inorganic salts in acid solution, e.g., $[Cr\{(NH_2)_2CS\}_3]Cl_3$.

In alkaline solution, a large number of heavy metal ions can be precipitated quantitatively as sulfides with thiourea. These precipitates are readily filtered, so that the method can be used for analytical determination of metal salts [12]. The production of light-sensitive PbS layers [13] and the purification of mercury- containing wastewater [14] are based on this reaction.

Thiourea forms clathrates (inclusion compounds) with branched aliphatic and cyclic hydrocarbons [15]. This property can be used, e.g., for separating branched and straight- chain aliphatic hydrocarbons [16].

Thiourea can be alkylated and acylated, and reacts with aldehydes and ketones. With formaldehyde, for example, it forms *N*-(hydroxymethyl)thiourea ($H_2N{-}CS{-}NH{-}CH_2{-}OH$), which condenses to resin-like products on heating [17]. By condensation of thiourea with chloroketones, diketones, hydroxyketones, oxocarboxylic acids, and similar ketone derivatives, a large number of heterocycles can be produced. From 2-haloketones or 2-haloaldehydes (in the enol form) 2-aminothiazole derivatives are formed:

1,1-Dihaloalkanes condense with thiourea to 1,3,5-dithiazines:

2-Hydroxyketones give 4-imidazoline-2-thiones:

With 2-oxocarboxylic acids (e.g., pyruvic acid) 2,3-dihydro-2-thioxo-4*H*-imidazole-4-one derivatives are formed:

Malonic esters react with thiourea to thiobarbituric acid:

2-Oxocarboxylic acid esters condense with thiourea to thiouracils, and 1,3-diketones to mercaptopyrimidines:

2.3. Production

Thiourea was first prepared by REYNOLDS by thermal rearrangement of ammonium rhodanide at ca. 150 °C:

$$NH_4SCN \rightleftarrows (NH_2)_2CS$$

As this is an equilibrium reaction and separation of the two substances is quite difficult, better methods of preparation have been investigated.

The reaction between carbon disulfide and ammonia or ammonium carbonate under pressure at ca. 140 °C has not achieved industrial importance [18].

Production of thiourea is now carried out by treating technical-grade calcium cyanamide ($CaCN_2$) with hydrogen sulfide or one of its precursors, e.g., ammonium sulfide or calcium hydrogen sulfide [19]. The calcium cyanamide must contain at least 23 % nitrogen and must be free from calcium carbide (CaC_2), as otherwise explosive acetylene is liberated by water or hydrogen sulfide.

In Germany, thiourea is produced in a closed system by reaction of calcium cyanamide with hydrogen sulfide:

$$CaCN_2 + 3H_2S \longrightarrow Ca(SH)_2 + (NH_2)_2CS$$

$$2CaCN_2 + Ca(SH)_2 + 6H_2O \longrightarrow 2(NH_2)_2CS + 3Ca(OH)_2$$

$$Ca(OH)_2 + CO_2 \longrightarrow CaCO_3 + H_2O$$

A reaction vessel is charged continuously with an aqueous suspension of calcium cyanamide and a mixture of hydrogen sulfide and carbon dioxide, such that the above reactions go to completion. The converted reaction mixture is removed continuously from the reactor and excess H_2S is removed by stripping. Wastegas from the reactor contains hydrogen sulfide, which is purified in a scrubber connected to the reactor.

The stripped thiourea solution is filtered to remove the precipitated calcium carbonate formed as one of the reaction products. The filtrate is evaporated in vacuum and thiourea is crystallized by cooling. It is filtered, washed, and dried in an air stream.

2.4. Environmental Protection

In Germany, the scrubbed waste gases resulting from the production and filtration of thiourea are treated in an incinerator. All installations where thiourea dust is handled are equipped with air extraction. The extracted air is collected and, together with the waste air from the product drier, is purified in a scrubber.

Mother liquors containing thiourea are removed batchwise from the production process and are used in high-temperature incineration processes to remove NO_x. Side products of low solubility separated from the mother liquor are incinerated externally in a licensed plant.

The precipitated calcium carbonate arising in the production of thiourea is reprocessed (e.g., in cement factories or brick works). This is a contribution to the conservation of natural lime resources.

2.5. Quality Requirements

The German producer gives the following specification for the standard product:

Thiourea	$\geq$ 99.0 %
Water	$\leq$ 0.30 %
Ash	$\leq$ 0.10 %
Rhodanide (SCN^-)	$\leq$ 0.15 %
Other N-containing compounds	$\leq$ 0.5 %
Iron	$\leq$ 10 mg/kg

Special qualities with higher purity are also produced.

2.6. Chemical Analysis

Tests of the content (purity) of thiourea can be carried out titrimetrically with Ce(IV) and potassium iodate solutions [20]. Since the commercial product is of relatively high quality, it is more efficient to determine the impurities as a means of quality control. The main impurity, dicyandiamide, is best determined by TLC. The incineration residue (ash) and the water content are also measured. A quantitative determination of sulfate, heavy metals, and rhodanide can also be carried out.

Traces of thiourea (e.g., in water) can be determined by HPLC (C_{18} reverse-phase with water as the mobile phase and subsequent UV detection at 245 nm) [21].

Reaction of thiourea with sodium nitrite in acetic acid solution to give thiocyanate, which gives a red coloration with Fe^{3+} ions, is also suitable for the determination of trace amounts. The red coloration is used to determine thiourea photometrically at 450 nm [22].

2.7. Storage and Transportation

Thiourea is packed in polyethylene bags ($\leq$ 50 kg) or in folding containers ($\leq$ 1500 kg). Bags and containers must be kept tightly closed, and in a cool, dry place. The contents must be protected from the action of light. Thiourea is not regarded as dangerous goods in transport regulations (RID/ADR, etc.).

2.8. Uses

Thiourea has a wide range of uses, e.g., for producing and modifying textile and dyeing auxiliaries [23], [24], in the production and modification of synthetic resins [25], in repro technology [26], in the production of pharmaceuticals (sulfathiazoles, tetramisole [27], and cephalosporins [28], in the production of industrial cleaning agents (e.g., for photographic tanks [29] and metal surfaces in general [30], [31]), for engraving metal surfaces [32], as an isomerization catalyst in the conversion of maleic to fumaric acid [33], in copper refining electrolysis [34], in electroplating (e.g., of copper) [35], and as an antioxidant (e.g., in biochemistry) [36].

Other uses are as an additive for slurry explosives [37], as a viscosity stabilizer for polymer solutions (e.g., in drilling muds [38]), and as a mobility buffer in petroleum extraction [39]. The removal of mercury from wastewater from chlorine – alkali electrolysis [14] and gold and silver extraction from minerals [40], [41] are also of economic importance.

2.9. Legal Aspects

Thiourea is included in international inventories of existing chemicals, e.g., EINECS (European Union), TSCA Inventory (United States), DSL (Canada), ACOIN and AICS (Australia), and MITI (Japan). In Germany and in the European Union, it is classified as a suspected carcinogen (MAK III B [42], [43]; EU cancer category 3). Similar evaluations have been made by the International Agency for Research on Cancer (Lyon, France) [44], and within the framework of the National Toxicology Program in the United States [45]. Within the European Union, thiourea must be labeled as a hazardous substance with hazard symbol Xn (St Andrew's cross – harmful), and R 22 (harmful if swallowed), R 40 (possible risk of irreversible effects), S 22 (do not breathe dust), S 24 (avoid contact with skin), and S 36/37 (wear suitable protective clothing and gloves). In the European Union Council Regulation on Existing Chemicals, thiourea is named in Annex I [46]. In Germany, the substance is classified in water hazard class 2 (hazardous for waters).

2.10. Economic Aspects

The quantity of thiourea produced and sold worldwide is ca. 10 000 t/a. The only producer in Western Europe is SKW Trostberg, Germany. Thiourea is also produced by Sakai Chemicals in Japan and at least seven Chinese companies.

According to estimations of SKW Trostberg, the largest producer, the quantity of thiourea produced worldwide is divided into the following main areas of use:

Intermediate in the production of thiourea dioxide	ca. 30 %
Ore leaching	25 %
Diazo papers	ca. 15 %
Catalyst in fumaric acid synthesis	ca. 10 %

The remainder is divided between smaller areas of use (Section 2.8).

The United States EPA carried out a survey of the uses of thiourea in the United States. It is used, for example, in animal glue liquefiers, in silver and metal cleaners, in the production of flame-retardant resins, and as a vulcanization accelerator [45].

2.11. Toxicology [42–44], [47]

Acute Toxicity and Local Tolerance. The oral LD_{50} for mice has been reported to be 1000 mg/kg [48], for rabbits 10 000 mg/kg [49], and for rats 1750 mg/kg [50] and 6200 – 6300 mg/kg [51]. After intraperitoneal administration LD_{50} values varying between 4 and 1340 mg/kg were found for rats [52], [53]. Lung edema and pleural effusion have been described as symptoms. The dermal LD_{50} is $>$ 2800 mg/kg for rabbits [50] and $>$ 6810 mg/kg for rats [51]. After inhalation of dust for 4 h (particle size 0.8 – 4.7 µm) LC_{50}

for rats was $> 170\,mg/m^3$ [50], after aerosol inhalation (10 % solution) $> 195\,mg/m^3$ [50]. An alcoholic solution (droplet size $< 10\,\mu m$) gave $LC_{50} > 900\,mg/m^3$ [51].

In skin tolerance tests (normal and abraded rabbit skin, 24 h application), slight to distinct erythema and slight edema were observed [50]. A 4 h application of 0.5 g gave no reaction [51]. Application of a 10 % solution into the conjunctival sac of a rabbit's eye gave no reaction [50], but 100 mg of the solid substance gave a slight reddening and swelling [51]. Thiourea does not have a sensitizing effect in the guinea pig [51].

Subacute and Chronic Toxicity. In long-term application of thiourea, the effect on the thyroid gland stands out [54]. The substance disturbs incorporation of iodine in the synthesis of thyroxine and thus leads to a release of thyrotropic hormone from the pituitary gland, followed by severe stimulation of the thyroid gland, resulting in hyperplasia, adenomas, and, under certain circumstances, formation of thyroid carcinomas. Administration of thyroxine extensively prevents these effects.

Nonspecific effects of thiourea include hemosiderosis in the spleen, lymph nodes, and intestinal villi [55], weight loss of the liver, kidneys and spleen [54], anemia, leukopenia, increased erythropoiesis, and reduced bone growth.

Some examples of long-term tests are given below: rats received 0.625 % thiourea in the diet for 14 days. This resulted in 52 % growth inhibition [56]; 2.5 g per kilogram food (over 13 weeks) did not affect the body weight of mice [57]. Administration of 2.5 ppm in the drinking water of rats over 13 weeks gave no reaction [58]; after $27.5\,mg\,kg^{-1}\,d^{-1}$ for 53 weeks in the drinking water normal growth was observed in rats [59]. Subcutaneous application in the mouse of $500\,mg\,kg^{-1}\,d^{-1}$ for 10 d led to a slight decrease in the colloid content of the thyroid gland [60].

Mutagenicity [42], [43], [47]. In the Ames test with *Salmonella typhimurium* (TA 98, 100, 1535, 1537, 1538; 10 – 5000 µg per plate) thiourea was shown to be nonmutagenic, with and without activation (S9 mix) [51], [61–63]. A DNA repair test with isolated rat hepatocytes (0.3 – 30 mmol thiourea) also gave negative results [51]. A further test of this type gave a slightly positive result, as did a test with Chinese hamster cells V79 [64]. A CHO/HGPRT cell mutation test [65], a test for mitotic recombination (*Saccharomyces cerevisiae* D3) [66], and a micronucleus test (rat, 2×350 mg/kg, oral) [50] were also negative. A host-mediated assay (mouse) with TA 1530, TA 1538 (125 mg/kg thiourea, i.p.) showed a slight increase in the mutation rate, but the same test with TA 1535 and *Saccharomyces cerevisiae* (1000 mg/kg thiourea, i.p.) did not [48].

Carcinogenicity. A cell transformation test with Syrian golden hamster embryo cells (0 – 100 g/mL) was negative [67].

Experiments on mice with different test periods (4 – 10 months) and dose levels (0.1 – 0.5 % in drinking water) showed a slight enlargement of the thyroid gland and slight thyroid hyperplasia [68]. Application of 2 % thiourea in the diet over 1.5 years led to hyperplasia and cystic changes in the thyroid gland, but not to carcinomas [69]. In rats receiving 0.25 % in drinking water for 5 – 23.5 months, adenomas and carcinomas in the thyroid gland were observed [70]; in other tests (0.2 % in drinking water) tumors in the orbita, nose, and ear regions [71] were observed as well as in the liver (0.01 – 0.25 % thiourea in the diet) [72].

Tumor formation is associated with excessive stimulation of the thyroid gland by thyrotropic hormone from the pituitary gland. The fact that thiourea has only a weak mutagenic potential also indicates an epigenetic mechanism for tumor formation. Since tumors are also found occasionally in organs other than the thyroid gland, thiourea is classified as a suspected carcinogen [42], [43].

Embryotoxicity. In mice and rats, maternally toxic oral doses of 1000 mg/kg body weight were found to be embryotoxic [73]. In rat fetuses, whose dams had received 2000 ppm in drinking water, maturation defects were apparent in the central nervous system, skeleton, and eyes [74]. These effects are attributed to the thyreostatic activity of thiourea. Therefore, at dosages which are not sufficient to inhibit thyroid function effects are not expected [42]. A single oral dose of 480 mg/kg was found to be

* EPDM = ethylene–propylene–diene terpolymers.

neither maternally toxic nor teratogenic in rats [75].

Absorption and Metabolism. In humans, thiourea is rapidly and completely absorbed from the gastrointestinal tract following oral administration. Most is excreted unchanged in the urine [76]. Small amounts appear as sulfate and ether sulfate, as shown by tests with radioactive material in rats [77]. A whole-body autoradiography with ^{14}C-thiourea showed enrichment and longer residence time in the thyroid gland compared with other tissues [78]. Following cutaneous application of 2 g/kg as an aqueous solution in rabbits, ca. 4 % of the dose was detected in the urine, but only 0.1 % after application of the solid [50].

Effects on Humans. Thiourea has been used temporarily in therapy because of its thyroid-depressant activity. After initial doses of 2 – 3 g/d, dosages of 100 – 200 mg/d were administered, and finally 25 – 70 mg was recommended as the daily dose. Doses of 10 – 15 mg/d were ineffective in 5 of 8 people [79]. Its use in therapy has been frequently associated with side effects, e.g., gastrointestinal disorders, pain in the muscles and joints, leukopenia, fever, and reddening of the skin. There are only a few reports on observations in the workplace [80], [81]. Apart from hypothyroidism, symptoms appeared which were similar to side effects known from therapeutic use.

In the use and processing of thiourea, contact dermatitis has occasionally been reported, e.g., on use in silver polish and diazo (blueprint) paper, sometimes after UV irradiation [82–86].

A Dutch expert committee recommended an occupational exposure limit of 0.5 mg/m^3 [47]. This value is also cited in the documentation of the German Research Association with reference to the thyroid gland [42], [43].

3. Thiourea Derivatives

3.1. Physical Properties

Melting points and solubilities of thiourea derivatives are given in [7], [9], [11].

The free energy of activation for rotation about the C – N bond determined by dynamic NMR spectroscopy is in the range $\Delta G^{+} = 29 - 50$ kJ/mol [87].

Various physical methods, e.g., neutron diffraction [88] and IR spectroscopy [89], confirm a strong contribution of the polar, planar structure I to the ground state:

I

Monoalkyl-substituted thioureas exist as mixtures of *E* and *Z* isomers . In monoaryl substitution products, the *E* isomer is preferred [90].

(*E*) (*Z*)

3.2. Chemical Properties

The chemistry of thiourea and its derivatives is dominated by two structural features:

1) The nucleophilicity of sulfur gives isothiuronium salts in good yields on protonation [91], alkylation, and arylation [9].
2) The polyfunctional character of the thiourea system can be used to synthesize 4-, 5-, 6-, and 7-membered heterocycles [9], [92].

Halogenation and oxidation reactions of monoaryl-substituted thioureas give 2-aminobenzothiazoles [93], important in the production of, e.g., polyester dyes [94].

3.3. Production

Methods for the production of thioureas can be divided into seven groups [11]:

1) Reaction of alkyl, aryl, and heteroaryl isothiocyanates with ammonia, or primary or secondary amines can be used universally, is simple to carry out on a preparative scale, and gives mono-, di-, and trisubstituted thioureas in good yields:

2) Reaction of primary amines with carbon disulfide is of fundamental importance for the synthesis of *N,N*-diaryl-substituted thioureas and results in quantitative yield with aromatic amines. Dithiocarbamates are formed as isolable intermediates (→ Dithiocarbamic Acid and Derivatives, Chap. 3.), which are converted to thioureas with loss of hydrogen sulfide:

Nitroarenes can also be used as starting materials if the reaction is carried out in an alkaline medium [95].

3) Primary and secondary amines react with thiophosgene, forming thiocarbamoyl chlorides as intermediates, which are then converted to di- and tetrasubstituted thioureas:

However, other thiocarbonic acid derivatives, e.g., thiocarbonylbisazoles or diesters of trithiocarbonic acid, react only with primary amines.

4) By analogy with the thiourea synthesis from ammonium thiocyanate, primary alkyl- and arylammonium thiocyanates are converted by thermolysis into monosubstituted thioureas in good yields:

5) Addition of hydrogen sulfide to alkyl- and aryl-substituted cyanamides offers an effective route to *N*-mono- and *N,N*-disubstituted thiourea derivatives by analogy with the industrial thiourea synthesis from calcium cyanamide:

6) For the production of sterically hindered, tetrasubstituted thioureas, sulfurization of the corresponding urea derivatives with phosphorus pentasulfide is suitable:

7) Cyclic thioureas can be obtained by the methods known for open-chain thioureas, and by the reaction of diamines with thiourea [96]:

3.4. Uses

Analysis. For the quantitative determination of thiourea compounds, titration with phenyl iodosoacetate is suitable [97]. Chromatographic methods have been developed for separation [98].

Table 4. Thiourea derivatives as plant protection agents and pesticides [107]

Thiourea derivative	CAS No.	Use	Generic name	Trade name	Producer
	[*28217-97-2*]	acaricide, anti-tick agent	chloromethiuron	Dipofene	Ciba-Geigy

	[*23564-06-9*]	fungicide, anthelmintic	thiophanate	Topsin Nemafax Verdamax	Nippon Soda May & Baker May & Baker

Because of their complex-forming properties [99], thiourea derivatives can be used as analytical reagents [100] and for the extraction of noble metals [101].

Industrial Applications. The thiourea derivatives listed in Table 2 are used as accelerators for the vulcanization of polychloroprene and ethylene – propylene – diene terpolymers (EPDM) [102].

N-Substituted thiourea derivatives are used as corrosion inhibitors, as antioxidants in the rubber industry, in electroplating processes [8], and in the production of light-sensitive materials [103].

Biological Activity. Some thioureas are used as active substances in human and veterinary medicine [104–106], as insecticides [107–109], and as rodenticides [110]. The structures of thiourea derivatives which are important as pharmaceuticals and as plant protection agents and pesticides are given in Tables 3 and 4.

3.5. Toxicology

The toxicological properties of a selection of alkyl- and aryl-substituted thiourea derivatives are described in [111].

More recent studies have dealt with metabolism and the effect of steric factors on the toxicity of *N*-phenylthiourea derivatives [112], and with the mutagenic, teratogenic, and carcinogenic properties of imidazolidine-2-thione (ethylenethiourea) [*96-45-7*], a metabolite of ethylene-bisthiocarbamate fungicides [113].

1. Introduction

Thorium has atomic number 90 and relative atomic mass 232.038. It was originally placed in group 4 of the periodic table under titanium, zirconium, and hafnium, following $_{89}$Ac. However, the $5f$ electron shell is filled in the series of elements from $_{90}$Th to $_{103}$Lr. In analogy to the lanthanides, in which the $4f$ shell is filled, these elements are therefore referred to as the actinides, thorium being the first in the series [1, 2]. Its similarity to cerium and its mineralogical occurrence in association with the rare earths and uranium confirm this placing. The number of thorium isotopes known thus far, all radioactive, is 25 [3]. The most common of these has the relative atomic mass 232, and five others occur naturally in the decay chains of uranium and thorium. First isolated by BERZELIUS in 1828 from the silicate mineral thorite, thorium attained industrial importance in the late 1800s as a component of gas mantles. By World War II, total consumption worldwide had amounted to ca. 8000 t, mainly for the production of gas mantles, reaching 250 t in some years. Thorium occurs in only a few regions of the earth's crust in minable amounts, although its average abundance is three to four times that of uranium [4]. After absorbing a neutron, thorium is transformed in several steps into fissile (i.e., fissionable by thermal neutron) ^{233}U. Thorium thus represents quantitatively by far the greatest energy reserve based on nuclear fission. Therefore, in the early years of nuclear technology, up to 900 t/a thorium was extracted and stockpiled as a strategically important raw material, and some hundreds of tonnes were irradiated in reactors, although less than 3 t of ^{233}U was obtained from this.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_001

However, for partly technical and partly economic reasons this route to energy production is now of little importance except in India. Therefore, since thorium is little utilized in the nonnuclear field, consumption since 1990 has declined to a few tens of tonnes per year.

2. Properties

2.1. Physical Properties

Formation and Decay. The most abundant thorium isotope (exceeding the abundance of the other isotopes by a factor of several millions) is ^{232}Th. Its concentration in the earth's crust obeys Harkins' rule, which states that even-numbered isotopes are more abundant than odd-numbered ones [5]. However, its concentration overall is more than twice that expected from the decrease in abundance of nuclides with increasing atomic number. The half-life of ^{232}Th (α decay) is 1.4×10^{10} a, the longest of all actinides, and a calculation based on the half-lifes of higher actinides shows that this concentration excess must be a result of the decay of primordial actinides such as plutonium and curium in the initial phases of the earth's history. Mineralogical evidence is provided by the fact that the very old thorium mineral bastnaesite, a thorium fluorocarbonate, is so far the only mineral in which traces of the longest-lived transuranic, the isotope ^{244}Pu with a half-life of 8.26×10^{7} a, have been detected [6].

As early as 1922, the isotopic ratio ^{208}Pb : ^{206}Pb and the age-proportional Th:U ratio in old ores were thought to indicate that a parent nuclide to thorium must have existed, whose half-life was estimated to be $(5.9–6.3)\times10^{7}$ a [7]. This closely matches that of ^{244}Pu.

Alpha decay of ^{232}Th leads to ^{228}Th, while in the uranium decay chain, ^{238}U gives the short-lived ^{234}Th and ^{230}Th, and decay of ^{235}U gives ^{231}Th and ^{227}Th. Because of the low concentration of ^{235}U (0.711 %) in natural uranium and the short half-lifes of the last two thorium isotopes, these are of little quantitative significance.

The thorium decay chain from ^{232}Th to ^{208}Pb is shown in Figure 1 [8].

The concentration ratio of ^{232}Th to ^{228}Th at equilibrium corresponds to the ratio of their half-lifes. In ^{232}Th irradiated in a reactor, an even higher proportion of ^{228}Th and of the follow-on daughter nuclides from ^{232}U decay chain is present, which is indicated, e.g., by the intensified 2.6-MeV γ-radiation from ^{208}Tl.

Neutron absorption leads to the formation of ^{233}Th from ^{232}Th. By two subsequent β decays ^{233}U is formed which decays to form the long-lived ^{229}Th (half-life 7340 a). The other thorium isotopes with mass numbers 212 – 225 are very short-lived α-emitters formed by decay of the corresponding uranium isotopes, and the isotopes ^{235}Th and ^{236}Th are short-lived β-emitters; all are produced by artificial transmutation and are of no industrial importance.

Like all other actinides, ^{232}Th also undergoes spontaneous fission with neutron emission, although, being the first member of the series, it has the longest half-life (i.e.,$>10^{21}$ a). The xenon isotopes expected as fission products can be found in old thorium ores, which also contain 1 – 10 cm^3 of helium per gram from α-decay. The helium can be boiled out with water.

Where tetravalent uranium is present in primary ores, it is usually associated with thorium, whose principal valence is also 4. Therefore, the thorium isotopes present come from all three decay chains (^{235}U, ^{238}U, ^{232}Th). The isotope ^{230}Th (ionium), a decay product of ^{234}U, is important because of its relatively long half-life (75 400 a) and, at equilibrium, is present at a level of 1.76×10^{-3} % of the proportion of uranium in the thorium.

The activity of freshly separated ^{232}Th passes through two activity maxima due to the formation of decay products. The first of these, which gives approximately a threefold increase in activity, is due to the six short-lived decay products of ^{228}Th (half-life 1.9 a) and occurs after ca. 5 weeks. The second increase begins after ca. 4 a when ^{228}Th is formed from ^{228}Ra (half-life 5.75 a), and the original radiation level increases almost fivefold after 40 a (see Fig. 2).

Pure thorium is a silvery-white, ductile metal, with low strength properties and chemical resistance [9]. It becomes gray on exposure to air. Finely divided thorium is pyrophoric. These disadvantages can be mitigated slightly by adding alloying elements. Solid thorium has the highest atomic density of all thorium compounds, which favors its use in nuclear reactors.

The physical properties and thermodynamic data of thorium are listed below. Thorium exists

Figure 1. Thorium decay chain

Figure 2. Change in reactivity with time of natural ^{230}Th plus ^{228}Th after separation from their daughters at time zero

in two solid phases, the α-phase (lattice constant 0.5068 nm) is stable at room temperature and is transformed to the β-phase (lattice constant 0.411 nm) at $1360 \pm 10\,°C$ (heat of transformation 3600 ± 125 J/mol). The phase transformation β-phase – liquid occurs at $1750 \pm 10\,°C$ (heat of fusion $13\,817 \pm 1256$ J/mol). Thorium has a *bp* of 4702 °C. The molar heat capacities are as follows:

α-phase	a:	25.5 J/mol
	$b \times 10^3$:	4.48 J/mol
	$c \times 10^{-5}$:	−0.51 J/mol

Table 1. Effect of production process on strength properties

Production process	Ultimate tensile strength, MPa	Tensile strength (0.2 % offset), MPa	Elongation, %
From iodide	125	42	40
By Ca reduction	175	105	60
Compressed and sintered thorium	245	175	35

where a denotes the linear, b the quadratic, and c the cubic term in the equation for the heat of transformation ($Q = a\,t + b\,t^2 + c\,t^3$)

β-phase	a:	15.70 J/mol
	b:	11.97 J/mol
liquid		46.06 J/mol

The vapor pressure p (atm) is given by

$$\log p = a - \frac{b}{T}$$

where T is the temperature in kelvin, and a and b are 27.84 and 129.67 J/mol for the α-phase and 25.10 and 124.02 J/mol for the liquid.

Thorium crystals have a density of 11.72 g/cm^3 at 25 °C; the apparent density of the cast metal is only 11.5 – 11.6 g/cm^3.

Mechanical, thermal, and electrical properties of thorium metal are very sensitive to the level of impurities, especially the carbon content. The level of impurities typically varies according to the method of production. The purest and hence most ductile metal, prepared from the iodide by the van Arkel process (see Chap. 6), is used only in exceptional cases.

The effect of the thorium production process on strength properties is shown in Table 1. The dependence of Brinell hardness (N/mm^2) on the metal treatment process is given below:

Annealing or sintering	400 – 600 N/mm^2
Moderate deformation (50 – 80 %)	600 – 800 N/mm^2
Strong deformation (10 × elongation)	1100 – 1500 N/mm^2

Figure 3 shows the temperature dependence of the mechanical impact strength as a function of carbon content. The linear coefficient of expansion of Westinghouse and Ames thorium is listed in Table 2. As in the case of carbon-containing steels, marked cold embrittlement occurs with carbon-containing thorium over a certain range of carbon content, whereas with pure thorium, embrittlement increases continuously with decreasing temperature.

Table 2. Linear thermal coefficient of expansion (α) of thorium

Temperature range, K	$\alpha \times 10^6$, K^{-1}	
	Westinghouse Th	Ames Th
298 – 473	11.2	10.8
473 – 948	12.3	11.8
948 – 1273	13.8	13.4
298 – 1273 *	12.6	12.4

* Mean value.

Figure 3. Effect of carbon content of thorium on impact energy [10]

The variation of thermal conductivity (W cm^{-1} K^{-1}) with temperature is given below [11]

100 °C	0.377
200 °C	0.389
300 °C	0.402
400 °C	0.419
500 °C	0.427
600 °C	0.444
650 °C	0.452

This property is affected only slightly by the content of impurities, whereas the electrical conductivity is much reduced by impurities. At room temperature, pure thorium has an electrical resistance of $14 \pm 1 \times 10^{-6}$ Ω/cm. With 0.03 % C, the figure is 18×10^6 Ω/cm, and with 0.2 % C, 37×10^{-6} Ω/cm – the temperature coefficient of resistivity being $(3.6 - 4) \times 10^{-3}$ K^{-1}.

Figure 4. Effect of temperature on state of activation
a) Thoriated tungsten (monoatomic layer); b) Thorium; c) Pure tungsten

Figure 5. Relative binding energies in the radium isoelectronic sequence

Thorium metal is superconducting below 1.368 K.

Thorium has a very low work function of thermal electrons [9] (Fig. 4). The emission of electrons from "thoriated" tungsten wires is up to four orders of magnitude higher than that from pure tungsten in the lower temperature region. (For further details, see Section 9.2.)

This low work function is in fact more likely to be a property of the oxidized surface of thorium, possibly formed by a suboxide such as "ThO," rather than of the pure metal. This is suggested by the fact that in Th^{2+} the electronic transition from $5f$ to $6d$ is facilitated by the extremely small difference in bonding energies (i.e., only 570 cm^{-1}), which is better than an order of magnitude less than the $5f-6d$ transition in neighboring elements and is a result of the interaction of a valence electron with the empty $5f$ shell, which can occur only with thorium (Fig. 5) [1, p. 144].

The standard electrode potential of thorium is

$Th \rightarrow Th^{4+}$ $E_o = -1.90$ V

It is therefore somewhat more negative than zirconium or aluminum. The overvoltage of H_2 on thorium is 0.38 ± 0.01 V. Thorium cannot be deposited electrolytically from aqueous solutions, and its deposition at a mercury electrode is also doubtful. Oxide-aquates are formed instead. The production of thorium metal by fused salt electrolysis is described in Chapter 6.

2.2. Chemical Properties

Thorium is nearly always tetravalent but, exceptionally, can have a valence of two (thorium hydride) or three.

In moist air, thorium metal oxidizes slowly at its surface even at room temperature. Oxidation proceeds in two stages. First, a surface layer of the dark gray hydride is formed by reaction with atmospheric moisture, the hydride is then oxidized, with formation of a strongly bonded oxide layer. Above 130 °C the rate of oxidation increases together with ablation of the oxide film, and at 450 °C, rapid oxidation begins with the evolution of heat. Thorium burns like magnesium, with an intense flame – pulverized thorium ignites spontaneously. Above 670 °C, thorium reacts with nitrogen to form Th_2N_3. Thorium reacts with hydrogen at 300 – 400 °C, with the evolution of heat, to form Th_4H_{15}, which itself decomposes above 1100 °C, probably forming ThH_2, a gray-black powder that ignites spontaneously and is isomorphous with ZrH_2. Thorium can therefore be melted only in an inert-gas atmosphere or in a vacuum.

Thorium reacts violently with the halogens and with sulfur on heating to 450 °C, producing a flame, and it reacts with fluorine even in the cold. The oxidation state of thorium is 4 in all the compounds formed. Thorium is hardly attacked at all by water, even when hot, but reacts at 800 –900 °C with water vapor to form ThO_2.

On heating with phosphorus, finely divided boron, or carbon, tetravalent compounds are formed immediately, as in the reaction with nitrogen. Alloys are formed with all actinides and lanthanides, iron- and platinum-group metals, alkali metals (except Li), Mo, W, Ta, Zn, Zr, Hf, Be, Al, and Si.

Thorium is stable toward dissolved or molten alkali and is attacked only slowly by dilute mineral acids. It is passivated in HNO_3, but the effect disappears in the presence of small concentrations of HF or H_2SiF_6 (0.05 mol/L), and thorium is then dissolved rapidly. Thorium dissolves in aqua regia and concentrated HCl.

Thorium salts generally contain tetravalent thorium. They have only a slight tendency to hydrolyze. A pH of 3.7 is required to remove the first hydrogen ion from the water molecule according to

$$Th^{4+} + H_2O \rightarrow Th(OH)^{3+} + H^+$$

The thorium ion forms anionic complexes with a large number of ions in acidic or neutral solution (e.g., CO_3^{2-}, $C_2O_4^{2-}$, SO_4^{2-}, HSO_4^-, PO_4^{3-}, citrate, and tartrate). Thorium forms positively charged complexes with F^- if the molar ratio of F^- to Th^{4+} is<2. Complexes are also formed with an excess of thiocyanide and nitrate. Thorium has a strong tendency to form double salts such as $K_2ThF_6 \cdot 4\,H_2O$, $NaTh_2(PO_4)_3$, $MnTh(SO_4)_3 \cdot 7\,H_2O$, and $ThSO_4HPO_4 \cdot 4\,H_2O$; it also forms basic salts such as $ThOCO_3 \cdot 2\,H_2O$. The strong adsorptive forces of the Th^{4+} ion, which are exemplified by the formation of stable colloidal solutions in salt solutions with full gel – sol reversibility, especially in the system Th^{4+} – NO_3 – OH^-, is used in industrial production of ThO_2-particles of high density.

Some of the salts have very low solubility in acids (e.g., the iodates, peroxides, oxalates, fluorides, phosphates, complex sulfophosphates, ferrocyanides, and the double salt potassium thorium sulfate); these are used industrially to separate thorium. For more recent separation processes, the fact that thorium nitrate forms complexes with tributyl phosphate (TBP) and other organophosphates that are soluble in organic solvents is of great importance. These are useful for separating thorium from the rare earths (RE).

Although the readiness of the valence electrons to occupy the empty inner $5f$ shell is too small for any oxidation states other than 4 to be stable, it is deemed to be sufficient for covalent bonding. This gives thorium also a remarkable catalytic activity.

3. Occurrence and Raw Materials

Primary thorium deposits occur in acidic granitic magmas and pegmatites. They are locally concentrated, but of a small size. Secondary deposits are found in placer deposits at the mouths of rivers in granitic mountain regions (e.g., in India, Indonesia, and Brazil). In these deposits, thorium is enriched along with other heavy minerals.

Thorium, together with the related rare earths, is believed to have remained in the silicate layers during the phase separation of the earth because of their affinity for oxygen. Wherever these elements have not become bonded in the apatites formed in the initial crystallization, thorium became concentrated in the acidic residual magmas, especially in the nepheline – syenite pegmatites, where it can be found at concentrations of ca. 80 mg/kg (Hungary) compared with the average level in granites (5 – 15 mg/kg Th). If these minerals have been formed at high temperature, uranium is also present because of the isomorphism of UO_2 and ThO_2, although at lower temperature in the presence of oxygen and water, uranium can migrate away as a hexavalent ion.

Since thorium minerals are attacked only slightly by reactive components of the atmosphere (e.g., oxygen, nitrogen) and by aqueous solutions, they have been deposited in a sedimentary sequence (monazite has a density of 4.3 –5.6) along with other heavy minerals such as magnetite, rutile, cassiterite, garnet, ilmenite, and zircon in placer deposits, which sometimes also contain gold. If any thorium was present in the rivers in solution, it was precipitated together with dissolved iron as carbonate and fluoride on entering the sea.

Because of its low water solubility, thorium is scarcely present in water, soil, plants, or animals, even if the sand under a biotope contains thorium.

Table 3. Thorium minerals containing >3 % Th (mean value)

Name	Formula	Th content, %	Principal deposits
Oxides			
Thorianite	ThO_2	45.3 – 87.9	Sri Lanka
Uranothorianite	$(U,Th)O_2$	15 – 48	Canada, Madagascar
Phosphates/silicates, carbonates			
Thorite	$ThSiO_4$	25.2 – 62.7	Langesundfjord (Norway)
Orangite	$ThSiO_4$		Madagascar, Idaho
Huttonite	$ThSiO_4$		New Zealand
Uranothorite	$(U,Th)SiO_4$	20 – 42	Mid-Norway, Blind River (Canada)
Cheralite	$(Ce,La,Pr,Nd,Th,Ca,U)(PO_4,SiO_4)$	25.9 – 27.7	Travancore (India)
Monazite	$(Ca,La,Y,Th)PO_4$	3 – 26	India, Brazil, and most other deposits
Thorogummite	$Th(SiO_4)_{1-x}(OH)_x$	18.2 – 50.8	Brazil, Jisaka (Japan)
Tscheffkinite	silicates of RE, Fe, Mn, Mg, Ca, Al, Ti, Th, U	$\leq$18.4	Madagascar
Pilbarite	$PbO \cdot UO_3 \cdot ThO_2 \cdot 2\,SiO_2 \cdot 4\,H_2O$	$\leq$27.4	Western Australia
Allanite	$(Ca,Ce,Th)_2(Al,Fe,Mn,Mg)_3(SiO_4)_3OH$	$\leq$3.2	Montana, Sri Lanka
Niobates/tantalates			
Pyrochlore	$(Na_4,Ca_2,U,Th)(Nb,Ta)_4O_{12}$	$\leq$10	Colorado
Euxenite	$(Y,Ca,Ce,U,Th)(Nb,Ta,Ti)_2O_6$	$\leq$4.5	Western Australia, Nigeria

Table 4. Composition of monazite concentrates

Constituent	India	Brazil	Florida beach sand *	South Africa Monazite Rock	Malagasy Republic

* Florida beach sand contains about 70 % monazite.
** Rare earth oxides, including Ce_2O_3.

More than 100 different ores contain thorium minerals. The most important are listed in Table 3. No deposits exist that are worth extracting for thorium alone, so it is almost always extracted as a coupled product with the rare earths, which themselves can be a side product of the production of other heavy minerals when they are in the form of monazite from a gravity concentration process.

The most widely occurring and important mineral is monazite, a phosphate of rare earths and thorium, in which the content of individual metals varies with the origin of the mineral (→ Rare Earth Elements, Chap. 2.). Typical compositions of monazite concentrates from five important deposits are given in Table 4 [12]. The currently known and extracted deposits amounting to ca. 1.3×10^6 t are in India and Malaysia (30 %); Egypt (20 %); Canada and the United States (15 %); and Brazil, Russia, and Australia (5 %); the remainder is in Indonesia, Nigeria, Nyasaland, and the Republic of South Africa. These deposits can meet the demand for the foreseeable future, so new deposits are not being sought.

The largest mining areas are in India in the province of Travancore, where the coastal sands over a distance of >70 km contain monazite in the form of honey-yellow grains up to several millimeters in size.

The sands are usually subjected first to simple gravity concentration, which yields a concentrate containing 65 – 80 % ilmenite ($FeTiO_3$), 3 – 6 % rutile (TiO_2), zircon ($ZrSiO_4$), 1 – 5 % sillimanite (Al_2SiO_5), and garnet [$(Fe, Ca, Mg)_3Al_2SiO_4$], as well as some cassiterite

(SnO_2) and a small amount of gold, together with 0.5 – 1 % monazite.

4. Production [13]

The principal production stages are the concentration of thorium minerals, extraction of thorium from them, purification, and conversion to the metal or desired compounds, usually ThO_2. Whereas up to 0.2 % impurities, including rare earths, have no detrimental effects on conventional applications, nuclear technology demands a much lower level of impurities (by one or more orders of magnitude), especially of neutron-absorbing elements such as rare earths and boron, for which additional purification processes have been developed.

4.1. Concentration

4.1.1. Ore Preparation

The methods used for ore concentration are different for primary and secondary deposits. The process used by Molybdenum Corp. in the United States is described here as a typical example of beneficiation of a *primary deposit*. The pegmatites, which are usually obtained by mining, are first coarsely and then finely ground. The ores are then subjected to a flotation process at 60 °C. This gives a 63 % concentrate of rare earths and thorium. The alkaline-earth carbonates are dissolved out of this with HCl, further concentrating the ore to 73 %. Thickening, filtration, and calcination yield a concentrate containing almost 90 % Th and RE suitable for further processing.

For ore preparation from Indian coastal sands (*secondary deposit*), the sand is subjected to gravity separation on dredges just off the coast; i.e., the sand that is collected from the seabed is wet sorted in batteries of separators. Alternatively, after removal of the coarse fraction, the sand is sorted in a dry state on the coast. The second step is magnetic sorting using a series of magnets of increasing strength. Magnetite and ilmenite are first removed by the weakest magnets; garnet is removed by magnets of the next higher strength; and coarse and fine monazite is successively removed in the next two stages, the paramagnetism of monazite being due to its rare-earth content. The monazite concentrate obtained has a purity of up to 98 %. Nonmagnetic residues are then usually treated by flotation to recover rutile, zircon, and gold, which are valuable byproducts.

4.1.2. Ore Digestion and Thorium Recovery

Monazite is fairly inert chemically. The industrial chemical ore digestion process, which was started in the last century, was first based on the simplest possible methods (i.e., treatment with hot, concentrated sulfuric acid in cast iron vessels, followed by selective precipitation by dilution with water). Because of the low rate of solution and the simultaneous presence of rare earths, thorium, and the complexing ions phosphate and sulfate in the solution, only slight variation in operation was possible, and success depended on following the formulations precisely and also on the composition and grain size of the monazite. A number of other processes were therefore developed to avoid these problems. For economic reasons, the only successful alternative method was to use alkaline digestion with hot sodium hydroxide solution. Although the process itself is a little more expensive than acid digestion, it removes phosphate and is therefore more suitable as a first stage before extractive separation to produce high-purity thorium. After some process development, it has been used mainly in the United States, India, and Brazil, where one of the target products is (or was) thorium of nuclear purity [14].

4.1.2.1. Acid Digestion

Digestion with sulfuric acid is usually carried out in two stages with 93 % acid at 210 – 230 °C (see Fig. 6). In the first stage, in which an acid excess of ca. 60 % is used, the reaction mixture thickens as reaction products are formed – first to a slurry and then to a solid gray mass. Then, fuming sulfuric acid is added, and treatment is continued for additional 5 h at the same temperature. The acid concentration chosen is the result of a compromise between the reaction rate (which increases with concentration) and the viscosity (which also increases with concentration,

Figure 6. Digestion with sulfuric acid and thorium concentration

thereby retarding the reaction). The completeness of the reaction depends on the grain size of the monazite sand, sand:acid ratio, temperature, and reaction time. Unfortunately, increasing the reaction temperature to 300 °C brings a risk of formation of insoluble thorium pyrophosphate and must therefore be avoided. Since the dissolution reaction is strongly exothermic, an upper limit exists to the rate of addition of monazite to the acid. In contrast, below 200 °C the reaction proceeds too slowly. If stoichiometric amounts of sand and acid could be used, the required amount of acid added would be only 60 % of the sand mass. However, to keep the salts formed in solution and prevent blockage of the reactive surface of sand by the formation of precipitates, the mass of acid used must be twice the mass of sand (see Fig. 7). To reduce acid consumption, reaction times of >5 h are used to minimize the volume of solution after dilution. After the pasty mixture is cooled to 70 °C, it is diluted with ten times its volume of cold water. The salts of rare earths and thorium remain in solution, while undissolved monazite rapidly settles out because of its high density. This can be recycled, and the

Figure 7. Effect of mass ratio of H_2SO_4: monazite sand at 300 °C and 30-min digestion on completeness of reaction
a) Completeness of reaction of thorium fraction; b) Completeness of reaction of sand (overall); c) Completeness of reaction of uranium fraction

finer and lower-density gangue materials are filtered off.

The subsequent separation of thorium and rare earths is based on the fact that thorium is almost completely precipitated as phosphate at pH values of ca. 1.3, while the main quantity of rare earths is precipitated later at a pH of ca. 2. Neutralizing agents such as sodium carbonate and ammonia must be added slowly and distributed homogeneously so that the pH limit is never exceeded, thus preventing local precipitation of rare earths, which do not redissolve. Furthermore, the slow rate of precipitation and the occlusive properties of the finely divided thorium precipitate must be kept in mind. The most uniform results would be obtained by diluting with pure water, but this is ruled out for practical reasons (i.e., excessive volume increase).

If the solution contains much uranium, simultaneous precipitation of thorium and rare earths by oxalic acid can be used – a selective, but expensive method of separation. Attempts have also been made to precipitate the rare earths first as double sulfates by adding sodium sulfate; to selectively precipitate thorium along with uranium from the solution as peroxides; or to precipitate rare earths from the concentrated solution by phosphoric acid and then evaporate the solvent to achieve precipitation of thorium as a double salt (sulfate – phosphate) [15].

An overview of the principal proven process variations is given in Figure 8. None of the processes is sufficiently selective to be used without subsequent removal of the rare earths from

Figure 8. Principal processes for extracting thorium from monazite acid leach liquor

thorium and vice versa. Also, sometimes one or more rare earths are the most marketable products and sometimes thorium is, the purity requirements being different in each case.

In the early 1950s, interest in thorium of nuclear purity suddenly increased in the United States. This led to the development of the Iowa process in the Ames Laboratories of the USAEC [16] in which H_2SO_4 digestion was linked with purification by solvent extraction of the Th and RE nitrates with TBP. After acid digestion, phosphate and sulfate were removed by oxalate precipitation; the oxalates were digested with alkali to form hydroxide precipitates, which were subsequently dissolved in HNO_3. The process was functionally reliable, but expensive, and produced a number of waste streams (variation 4 in Fig. 8, with details in Fig. 9).

4.1.2.2. Alkaline Digestion

As with acid digestion, treatment with sodium hydroxide solution (Fig. 10) is limited by a number of factors. If the temperature is too high,

Figure 9. Iowa process for separating thorium, rare earths, and uranium from monazite sulfate

a difficultly soluble thorium oxide is formed and too much uranium appears in the filtrate. If alkali concentrations are too low, the dissolution process takes too long. The optimum values appear to be 30 – 45 % sodium hydroxide solution at ca. 140 °C and a reaction time of 3 h. However, these comparatively mild reaction conditions require finely ground monazite sand (particle size<45 µm) to ensure adequate reaction. After filtration the filter cake contains rare earths and thorium as hydroxides and uranium as sodium diuranate; all of the phosphate is present in solution in the filtrate as trisodium phosphate. On cooling this below 60 °C, $Na_3PO_4 \cdot 10\,H_2O$ crystallizes. The uranium content of trisodium phosphate increases with the amount of dissolved SiO_2, and it must be recrystallized before it becomes a salable byproduct.

The hydroxides are dissolved in 37 % HCl at 80 °C. After filtering off the undissolved material, 47 % NaOH is added, and thorium along with uranium almost completely precipitates at pH 5.8. However, the alkaline filter cake must not be completely dried; otherwise, some Ce^{4+} is formed by contact with air, and this liberates chlorine from HCl. The rare earths are precipitated by further increasing the pH. Neutralization can be carried out with NaOH residues from

Figure 10. Caustic soda process for recovery of thorium from monazite

the filtrate from alkaline digestion, provided concentrations of phosphate are low enough as not to precipitate insoluble RE phosphates.

If thorium and uranium are to be separated from rare earths by solvent extraction, the filter cake from alkaline digestion is preferably dissolved immediately in HNO_3. However, complete dissolution of thorium cannot always be guaranteed, especially in the presence of titanium hydroxides, which bind large amounts of thorium. The good solubility of ThO_2 at 10 bar and 230 °C in HNO_3 was only discovered in 1986 [17], and has hitherto not yet been utilized on an industrial scale.

4.2. Fine Purification by Solvent Extraction

In recent decades, purification of chemically similar substances by techniques involving repeated transitions between solid and liquid phases has been replaced by technologically simpler liquid – liquid extractions. At the same time, purity requirements for thorium and its compounds have become more strict. Especially in nuclear technology, concentrations of elements with a high parasitic neutron capture cross section must be low. (For example, the maximum permitted concentrations equivalent to 4 mg/kg boron are only 8 mg/kg Sm, 2 mg/kg Er, or 1 mg/kg Gd.) Thus, the process of multiple solution and precipitation or recrystallization to separate rare earths from each other or from thorium and uranium has been replaced by multistage countercurrent solvent extraction methods. However, to give suitable distribution coefficients between the aqueous and organic systems, the chemical bonding of the ions that take part in the exchange must not be too different in the two systems. Thus, stable complexes of thorium and uranium that are soluble only in water,

especially those with sulfate and phosphate ions, are unsuitable.

Hence, attempts to extract thorium and uranium directly from monazite sulfate solutions with TBP in organic solution were unsuccessful. Only the use of extraction media with strongly cationic character enabled successful extraction from these solutions to be carried out. Whereas the anionic character of UO_2^{2+} is strong enough for it to bond to quaternary nitrogen (in amines dissolved in organic solvents), the situation is less favorable in the case of Th^{4+}. Some distribution coefficients are given in Table 5 (see next page), which also shows the clear difference between thorium and uranium. This difference favors branched primary amines.

Amex Process. The use of a combination of different amines in three consecutive cycles (see Fig. 11) is the basis of the prototype scale Amex process [18], which enables pure products (U, Th, RE) to be obtained directly from diluted solutions of monazite in sulfuric acid. However, in the absence of any large demand, this flow scheme has not yet been tested on a full scale.

Solvent Extraction with TBP. In the absence of phosphate ions (e.g., in the case of oxidic and carbonate-containing thorium ores) or if phosphate ions have been previously removed in the alkaline treatment method, the U, Th, and RE nitrato complexes can be separated and purified by extraction with TBP in an organic solvent, preferably in kerosene. The overall process is simple and easily controlled. The effect of the molarity of nitric acid on the distribution coefficients of rare earths, uranium, and thorium is shown in Figure 12. With a mean acid concentration of 3 mol/L, the distribution coefficient (organic/aqueous) for rare earths is 0.02, for thorium 1, and for uranium 20, so that a multistage separation is possible [19]. Trivalent metallic

ions such as Fe^{3+} can mask residues of phosphate. A suitable flow scheme is shown in Figure 13. Solvent extraction, which is optional in the purification of natural thorium compounds, is the only feasible method of separating thorium, ^{233}U, and fission products after irradiation in a reactor.

Figure 12. Effect of acid molarity on distribution coefficients (organic – aqueous phase) of nitrato complexes in TBP – kerosene extraction
a) Uranium; b) Thorium; c) Rare earths

In an intermediate route that can be used in the presence of high concentrations of sulfate but in the absence of phosphate (e.g., in residual solutions from uranium extraction in the Canadian Blind River district), thorium is extracted with di(2-ethylhexyl)phosphoric acid.

5. Important Compounds

5.1. Thorium Oxides [20]

Two compounds, ThO and ThO_2, exist in the oxygen – thorium system. The black compound ThO, which crystallizes with the sodium chloride lattice, is known only from coatings on the metal. It is probably an interstitial compound with an electron deficit structure. When ThO_2 is heated in an electric arc, ThO band structures appear in the spectrum.

The compound ThO_2 is the stable, well-known oxide, being formed if either a salt that contains a volatile anion or the oxidaquate is strongly heated. It is obtained as a very fine powder by precipitating and then strongly heating thorium oxalate, according to

$$Th(NO_3)_4 + 2\,H_2C_2O_4 \cdot 2\,H_2O \rightarrow Th(C_2O_4)_2 \cdot 2\,H_2O + 4\,HNO_3 + 2\,H_2O \text{ (at 60 °C)}$$

and

$$Th(C_2O_4)_2 \cdot 2\,H_2O + O_2 \rightarrow ThO_2 + 4\,CO_2 + 2\,H_2O \text{ (at 650 °C)}$$

At pH 1 and with careful temperature control, the reaction with oxalic acid leads to a crystalline precipitate with good filtering properties. Precipitation can be carried out selectively also in the presence of trivalent metals, uranium, and

Figure 13. Thorium purification by solvent extraction with TBP
– Aqueous phase; - - - 40 vol % TBP in kerosene

titanium. Several other 1,2-dicarboxylic acids have been tested as alternatives, but only tetrachlorophthalic acid gave significantly improved selectivity against the rare earths [21].

The structure, decomposition temperature used, and calcination temperature can affect the rate of reaction of ThO_2 in other reactions. For example, ThO_2 freshly prepared by low-temperature thermal decomposition of thorium oxalate (*meta*-ThO_2) is catalytically active and fairly soluble in acids, whereas thorium oxide calcined at high temperature is very slowly attacked by acids. It can be dissolved only in hot, concentrated H_2SO_4 or in concentrated HNO_3 in the presence of F^- ions. Physical properties of ThO_2 are listed below [22]:

Color	white
Crystal system	face-centered cubic
Density (X-ray, 25 °C)	10.00 g/cm^3
Linear expansion from 25 °C	9×10^{-3} at 1000 °C; 20×10^{-3} at 2000 °C
Thermal conductivity	
(100 °C)	0.10 W cm^{-1} K^{-1}
(600 °C)	0.04 W cm^{-1} K^{-1}
Melting point	3370 ± 30 °C
Entropy (25 °C)	65.3 J K^{-1} mol^{-1}
Heat of formation from elements (25 °C)	−1227.6 kJ/mol
Free energy of formation from elements (25 °C)	−1170.0 kJ/mol

The vapor pressure (atm) between 2180 and 2865 K can be calculated according to:

$$\log p = 8.00 - 3517/T$$

(ThO_2 dissociates partially into ThO and O; at low oxygen pressure the vapor pressure is somewhat higher.) The temperature dependence of the molar heat capacity (J/mol) between 298 and 3000 K is

$$C_p = 69.3 + 9.71 \times 10^{-3}T - 9.19 \times 10^{-5}T^{-2}$$

Two crystal forms are known, i.e., a tetragonal modification similar to rutile that crystallizes from borate melts and a cubic form that crystallizes from phosphate melts. The lattice constants and densities are very similar to those of the metal since the oxygen occupies interstitial locations. However, these densities are not reached by sintered oxides (maximum values: ca. 10.2 g/cm^3). Thorium dioxide melts at 3370 °C and thus has the highest melting point of all ceramic materials. The tendency of *meta*-ThO_2 to form colloidal solutions (thorium oxidaquate) in the presence of nitrate ions is important, because these can be dried to form stable gels that can be sintered to give high-density ceramic bodies. Another important property of ThO_2 is the emission of long-wave red light on

heating (a historical test of purity), and the shifting of the emitted wavelength further into the visible region by the addition of rare earths, especially cerium, which is an essential feature of gas mantle technology (see Section 9.2 for further details).

Coatings of ThO_2 on tungsten are used to promote the emission of electrons from incandescent cathodes. These coatings must be thin and uniform; they are produced by a simple process of dipping the cathodes into suspensions of thorium oxidaquate and various finely dispersed thorium oxide slurries or by electrophoretic deposition of the oxide from alcoholic suspensions. They must be "formed" by heating the cathodes to 2900 – 3000 °C.

Thorium oxide forms mixed crystals with a number of oxides of the actinides (e.g., U, Np, and Pu), with no miscibility gap. No phase transformation occurs up to the melting point.

When ThO_2 is used to form ceramics, for dimensional accuracy of the preformed bodies (crucibles, nuclear fuel pellets) the powders used must shrink by a small but definite amount during sintering/densification. Choice of the powder involves a compromise between less good sintering properties and minimized shrinkage. The *meta*-ThO_2 is preferably precalcined in an atmosphere of steam at 800 – 1000 °C before itis formed by pressing or slip casting. The effect of precipitation temperature and calcination temperature on the specific surface area of the powder is shown in Figure 14 [23].

Figure 14. Effect of temperature on the specific surface of thorium oxide from thermal decomposition of thorium oxalate

5.2. Thorium Halides

An overview of the properties of thorium halides is given in Table 6.

5.2.1. Thorium Tetrafluoride

Precipitation of thorium salt solutions with HF leads to the formation of gelatinous, white precipitates of ThF_4 hydrates with 8, 4, or 2 molecules of water of crystallization, but these hydrolyze to form mixtures of ThO_2 and $ThOF_2$ even on careful drying. Anhydrous ThF_4 can be obtained only by fuming ThF_4 hydrates many times with NH_4F or by dehydration in a stream of dry HF at 300 – 400 °C. Thorium tetrafluoride is therefore produced industrially by reaction of ThO_2 and HF in the gas phase:

$$ThO_2 + 4\,HF \rightarrow ThF_4 + 2\,H_2O$$

At 566 °C the reaction is exothermic and at first proceeds rapidly, but thermodynamic equilibrium is attained very quickly, leaving an unreacted excess of HF. At lower temperature, the reaction goes to completion but proceeds much more slowly. A schematic of the production of thorium fluoride from the nitrate via the oxalate, as carried out by the National Lead Company (Fernald, Ohio), is shown in Figure 15 [11, p. 153]. The plant consists of four stainless steel tubular reactors arranged in series, each provided with exterior heating and interior screw conveyors made of Inconel. A countercurrent flow system with graded temperature increases utilizes HF to give complete conversion of ThO_2. However, to obtain ThF_4 that does not contain oxide – fluoride, it was necessary to use excess anhydrous HF and produce and sell byproduct aqueous HF (70 %). New plants will probably be operated as fluidized-bed reactors following experience with uranium.

Thorium tetrafluoride is formed as a solid residue when enriched $^{235}UF_6$ is stored. The ^{234}U contained in uranium, which is also enriched, decays to form $^{230}ThF_4$. This remains behind after steaming out the UF_6 container and must be scrupulously removed because of its high α-toxicity.

In the electrolytic production of thorium from a fluoride melt, the double fluoride $KThF_5$ can be used as the starting material. The $KThF_5$ can

be precipitated by adding KF to a solution of thorium nitrate according to

$$Th(NO_3)_4 \cdot 4\,H_2O + 5\,KF \cdot 2\,H_2O \rightarrow KThF_5 + 4\,KNO_3 + 6\,H_2O$$

and is dried at 120 °C to give a product free of water of crystallization.

5.2.2. Thorium Tetrachloride

Depending on conditions, thorium tetrachloride crystallizes from aqueous solution with 11, 9, 8, 7, 4, or 2 molecules of water of crystallization, but oxide – chlorides are formed on drying. Anhydrous $ThCl_4$, like anhydrous ThF_4, can be produced only by reaction in the gas phase. All reactions that simultaneously reduce and chlorinate ThO_2 are suitable (see overview in Table 7), for example, chlorination of a mixture of ThO_2 and C above 600 °C:

Table 7. Reaction of chlorine and ThO_2 with reducing agents

ThO_2 type	Reducing agent	Temp., °C	Time, h	Yield, %
$Th(C_2O_4)_2$	carbon	700	2	99
	CCl_4	800	4	10
↓ >675 °C	sulfur	800	2	98
	C_3Cl_8	400	5	25
ThO_2	NH_4Cl	425	4	0
$Th(C_2O_4)_2$	carbon	600	2.5	99
	CCl_4	300	5.5	92
↓ 445 to 525 °C	sulfur	500	3	99
	C_3Cl_8	400	4	92
ThO_2	NH_4Cl	500	1.5	99

$$ThO_2 + 2\,C + 2\,Cl_2 \rightarrow ThCl_4 + 2\,CO$$

Because the $ThCl_4$ formed contains carbon as an impurity, it must be distilled at 942 °C. This step is complex due to the very hygroscopic and aggressive nature of the chloride. Distillation is not necessary if thorium oxalate is chlorinated with CCl_4 with a small addition of chlorine as a catalyst according to

$$Th(C_2O_4)_2 + CCl_4 \rightarrow ThCl_4 + 2\,CO + 3\,CO_2$$

The reaction is carried out at temperatures up to 525 °C in several stages in a graphite reactor.

5.2.3. Thorium Tetraiodide

Thorium tetraiodide has an intense yellow color, an *mp* of 566 °C, and a *bp* of 837 °C, and can be produced by reaction of the elements. Thorium tetraiodide reacts with excess thorium to give subiodides of trivalent and divalent thorium, depending on the relative amounts of reactants and the temperatures and pressures used. Like the other halides, it can in principle be produced by reaction of intimate mixtures of carbon and ThO_2 with elementary iodine. In the production of pure metallic thorium, the main use of ThI_4 , itis not isolated as a separate product but is used only as an intermediate for gas-phase matter transfer between crude and pure thorium in the van Arkel – de Boer process (see Chap. 6) [24].

5.3. Other Compounds

Thorium Nitrate. The compound from which almost all other thorium compounds are produced is thorium nitrate, $Th(NO_3)_4 \cdot 6\,H_2O$, which is highly soluble in water at room temperature (65 wt %). Evaporation of the aqueous solution yields the tetrahydrate (one of seven hydrates) in the form of a finely crystalline white powder [25].

Thorium Hydrides. The hydrides ThH_2 and ThH_4 are known. On reduction of ThO_2 with excess magnesium in the presence of H_2, a somewhat substoichiometric, highly flammable powder is formed, which is isomorphic with ZrH_2 and pseudoisomorphic with ZrC_2 and ThC_2. The other compound, which is also substoichiometric, $ThH_{3.75}$, has a cubic crystal structure that does not resemble that of the metal. Both compounds can be used to produce finely divided thorium metal since they release all their hydrogen at 900 °C. Anhydrous thorium halides can be obtained by reaction of the hydrides with hydrogen halides.

Thorium hydroxide, $Th(OH)_4$, is formed by precipitation from solutions of salts by adding alkali. This compound is not a true hydroxide, but an oxidaquate ($ThO_2 \cdot x\,H_2O$), a stable colloid that remains amorphous up to 340 °C.

Thorium peroxide, $Th_2O_7 \cdot 4\,H_2O$, is formed as a sparingly soluble precipitate when H_2O_2 is added to thorium salt solutions. Only the actinides react in this way. The reaction can be used to separate thorium from the rare earths.

Thorium Nitrides. The compounds Th_2N_3 and ThN are known. The first, Th_2N_3, is a hexagonal, dark red compound, which is formed from the elements, and decomposes in the presence of water to form NH_3 and ThO_2.

ThN has the face-centered cubic structure like the nitrides of uranium, lanthanum, and cerium, in which nitrogen has a quasimetallic character similar to that of carbon.

Thorium Phosphide and Borides. The corresponding phosphide ThP_4 is stable toward all the usual solvents. The two borides ThB_4 and ThB_6 are also very stable, hard materials, the latter forming dark red crystals.

Thorium Carbides. The mono- and dicarbide exist, although both compounds have a substoichiometric composition (i.e., 0.97 and 1.90). The monocarbide crystallizes with a face-centered cubic structure. The dicarbide is monoclinic up to 1410 °C and tetragonal above this temperature. The densities of ThC and ThC_2 are 9.6 and 8.76, respectively, and the melting points 2500 °C and 2640 °C. Depending on the availability of carbon, the carbides are formed readily from the elements or by reaction of an intimate mixture of graphite and thorium oxide at 1400 °C:

$$ThO_2 + 4\,C \rightarrow ThC_2 + 2\,CO$$

ThC has a metallic appearance and a thermal conductivity comparable to that of thorium metal. The dicarbide is readily oxidized to ThC at high temperature in the presence of oxidic substances. Partial mutual substitution of O_2, N_2, and carbon is possible, leading to relatively thermally stable compounds of the type $Th(O_{1-(x+y)}C_xN_y)$ when the sum of x and y is <0.6. The formation of solutions of carbon in thorium is described in Section 8.1.1.

Thorium sulfides are not readily formed from aqueous solution, but are formed by reaction of the elements. The compound ThS, which has a metallic appearance, is formed first and then converted in several stages to ThS_2 via the orthorhombic Th_4S_7 and other intermediates.

Thorium sulfate is important mainly because it is formed when monazite is digested with H_2SO_4. Thorium sulfate forms five different hydrates, which contain up to nine molecules of water of crystallization. Also, sparingly soluble double salts are formed with alkali-metal sulfates.

Thorium Carbonate. When thorium salt solutions react with alkali-metal carbonate, a poorly defined basic carbonate of the type $ThOCO_3 \cdot 8\,H_2O$ precipitates. It dissolves in an excess of alkali-metal carbonate (similarly to the corresponding uranium) to form relatively stable complex double carbonates of the type $Na_6Th(CO_3)_5$ or $(NH_4)_2Th(CO_3)_3 \cdot 6\,H_2O$. Thorium hydroxide does not precipitate from solutions of these substances.

6. Production of Pure Thorium Metal

Because of thorium's strongly negative standard electrode potential, its compounds cannot be reduced to the metal with carbon or hydrogen. The route to thorium metal is therefore reaction of the oxide or a halide with metals, electrolysis in molten salts, or thermal decomposition of a halide. The principal reactions that have led to production processes are summarized below:

1) Electrolysis of fused salts:
   $KThF_5$ in NaCl
   ThF_4 in NaCl – KCl
   $ThCl_4$ in NaCl – KCl
2) Reduction with reactive metals:
   ThO_2 with Ca
   $ThCl_4$ with Mg
   ThF_4 with Ca
3) Thermal dissociation of ThI_4

The results of the processes are listed in Tables 8, 9, 10, 11 [11, pp. 170 – 171].

* Chemical analysis.
** Spectrochemical analysis.

In the production of thorium metal, problems arose because of its highly reactive nature and sensitivity to both air and moisture, as well as its high melting point (1750 °C). The following four production methods have been tested on a full scale:

(1) reduction of fluorides and chlorides; (2) reduction of ThO_2; (3) thermal decomposition of ThI_4; and (4) fused salt electrolysis.

Reduction of ThO_2 with calcium metal was first carried out in the United Kingdom at 1200 °C on a pilot plant scale in a reactor lined with CaO. In the United States, the reaction was carried out in molten $CaCl_2$ in an argon atmosphere to provide a more coarse-grained product, the heat of reaction being insufficient to melt the thorium. Both processes give thorium sponge, which requires many further processing stages. These production processes were abandoned because of the high temperatures required and the cost of the apparatus.

Fused Salt Electrolysis. In fused salt electrolysis, $KThF_5$ is used as a 15–20 % mixture with NaCl to give a eutectic. Thorium is produced in an argon atmosphere as a nonadherent finely crystalline powder deposited on molybdenum cathodes in graphite cells at 900 °C, using a current density of 20 A/dm^2. In fused salt electrolysis, only Cl_2 is formed at the anode, and the buildup of thorium powder in the electrolysis vessel causes short circuits. Thus, batchwise operation must be used. A continuous method of operation is possible if $ThCl_4$ is used in a mixture of NaCl and KCl as electrolyte at 800 °C with strict exclusion of moisture. A very pure, coarse-grained thorium metal is obtained. Plants of this type were operated briefly in the United Kingdom, the United States, and the Soviet Union.

Thermal decomposition of ThI_4 yields an extremely pure, ductile thorium metal. Thorium iodide is usually produced from impure metal pieces, which are first heated in a muffle furnace to>500 °C for 24 h in a vacuum, and then reacted with iodine vapor, which is vaporized at 260 °C. Thorium iodide is formed between 450 and 480 °C, and purified by distillation. Thorium metal is deposited from the iodide on incandescent filaments of tungsten or thorium at 900–1700 °C. The temperature range between 500 and 900 °C must be avoided because the tetraiodide decomposes to form thorium and nonvolatile ThI_3 at a little over 600 °C. The total reaction (formation of ThI_4 and decomposition) is carried out in long, stationary, heated tubes filled with iodine vapor. Concentric perforated sheet metal tubes retain unreacted pieces of crude thorium at the walls of the tube, and pure thorium is deposited on heated filaments at the center. The thickness of the thorium rod that forms in the center is limited only by the electric current used, which eventually reaches several hundred amperes. Both decomposition of the iodide and electrolysis give very pure metal, but these processes do not give high throughputs or yields in the present state of the technology.

Reduction of Halides. The larger quantities of thorium metal used in the nuclear industry are produced on an industrial scale mainly by the reduction of halides. The fluoride and chloride are not equivalent, as can be seen from the reaction enthalpies (Table 13). Thorium fluoride can be reduced only by calcium, whereas a choice of sodium, calcium, and magnesium exists for the reduction of the chloride. Two processes were developed in the United States almost simultane-

Table 13. Free-energy change in reduction of thorium compounds to metallic thorium

ously: the reduction of $ThCl_4$ with sodium amalgam (Metallex process, Oak Ridge, 1954 [26]) and reduction with magnesium in the Kroll process, which was favored because of the price of magnesium and its lower sensitivity to oxygen (1956).

Metallex Process. The flow diagram of the Metallex process, which requires relatively simple equipment, is shown in Figure 16. Originally, $ThCl_4$ was dissolved in propylenediamine and reacted with liquid sodium amalgam. However, this step was then replaced for cost reasons by

Figure 16. Schematic of Metallex process

direct reaction of solid thorium chloride with the amalgam at 180 – 300 °C in a kneader mixer, a conversion of 97 % being obtained after 30 min. Excess sodium and sodium chloride were removed by washing with dilute HCl, and solid $ThHg_3$ was removed from excess Hg (in which thorium metal is soluble to<0.1 % at room temperature) by means of a filter press. Thorium amalgam was then decomposed in a steel retort at 1100 °C in vacuum, to remove mercury and produce a sintered solid. Since mercury has a high parasitic neutron capture cross section and can also attack the aluminum cladding on thorium rods in the reactor, it must be rigorously excluded. The process is consequently not without risk.

Kroll Process. The Kroll process, in which thorium chloride is reduced with magnesium [27], was developed at about the same time by the National Lead Company of Ohio. Although this process was originally expected to have a wide application for the treatment of all air-sensitive transition metals, it has in fact become widely used only for titanium, zirconium, hafnium, and thorium. In further development of the process by Ames Laboratories, thorium chloride is completely reacted at 850 – 950 °C in a furnace provided with exterior heating, by using twice the stoichiometric quantity of magnesium to give a Th – Mg alloy (Fig. 17). This alloy melts and forms a compact regulus. Magnesium chloride and excess magnesium are then distilled off at 950 °C in a high-vacuum furnace (Fig. 18) and collected in collection vessels.

Reduction of ThF_4 with Calcium. Quantitatively, the most important method for producing thorium of nuclear purity in the United States was reduction of ThF_4 with calcium metal. The process developed by Ames Laboratories and Iowa State University [28] was analogous to the

production of uranium metal. However, when calcium metal reacts with ThF_4, the heat of reaction is insufficient to melt the thorium metal. Additional heat is therefore generated by reacting $ZnCl_2$ with calcium metal. This also produces a lower-melting thorium – zinc alloy and a lower melting point eutectic of CaF_2 and $CaCl_2$. The process requires careful preparation of the reactants since most of the metallic impurities in the reactants end up in thorium. Calcium metal must be sieved to remove fine-grained material after preliminary size reduction because this material contains most of the impurities. Zinc chloride must also be of high purity; it must be anhydrous and not too fine grained, otherwise the reaction with calcium can take place prema-turely. The reduction furnace is illustrated in Figure 19. The furnace pot (e), which is made of nonscaling steel, is placed inside the muffle (g). This is heated by three heating elements (d, f, h), outside which is a lining of calcined dolomite. The reaction mixture consists of 75.3 kg of ThF_4, 27.22 kg of granulated calcium metal, and 7.26 kg of anhydrous $ZnCl_2$. A layer of dolomite powder is placed above and below the reactants to protect the walls. The furnace is heated to 660 °C, and when the contents reach 475 °C a strongly exothermic reaction begins, producing a Zn – Th alloy containing 18 mol % Zn. The furnace is operated behind safety walls because deflagrations occasionally occur. After cooling, the slag is removed, and 90 % of the zinc can be distilled off in vacuum (<27 Pa). The thorium sponge is cooled in a protective gas and then inductively melted in a BeO crucible in vacuum. The remaining zinc evaporates, and the thorium is cast in graphite molds (yield 94 – 86 %).

7. Metalworking [11, pp. 222 ff], [29, 30]

Most production processes lead to thorium powder or sponge. This must therefore be compacted by sintering or melting before it can be worked in a metal-forming process. In the literature, densification by powder metallurgy is described in less detail than melting and casting.

Melting and Casting. To cast thorium metal, it is first melted at 1800 °C by inductive heating in vacuum to avoid the danger of picking up O_2 and N_2. Also, zinc left behind from the production process (reduction of ThF_4 with Ca, see section page 25pp. 22 –23) must be evaporated, and pickup of impurities from the crucible material must be as low as possible. For this, either zinc is removed first in graphite crucibles at a temperature at which thorium hardly picks up any carbon from graphite (1300 °C) and the actual melting is carried out later in BeO crucibles, or both processes are carried out together in a stabilized ZrO_2 crucible. Thorium metal has a very low heat of fusion and, when fused, attacks all known crucible materials, so that excessive heating must be avoided. Both the service life of the BeO crucible and the limitation of pickup of impurities by thorium are only moderately satisfactory.

A two-stage electrode-consuming arc melting process is a better alternative for producing the cylindrical ingots generally used in nuclear technology. The molten thorium metal is subsequently solidified in water-cooled copper

Table 14. Average analyses of thorium ingots

crucibles. The pieces of thorium sponge obtained from the first dezincification are sawed into strips in chambers filled with inert gas and then welded together to form electrodes. However, metal is lost in this laborious operation, and attempts have therefore been made to replace it by hot plastic forming of the sponge (casting or compaction). The properties of the ingots obtained by induction and arc melting are listed in Table 14.

In subsequent metalworking, thorium resembles soft iron in its ductile behavior. Even the presence of several percent oxygen does not cause problems, because oxygen is virtually insoluble in thorium and therefore only contained in inclusions of ThO_2. To prevent surface oxidation – especially of the small pieces used during hot working by, e.g., rolling, hammering, or extruding – the pieces are encased in soft copper or iron cladding, which is later dissolved in acid. Welding of thorium is possible only in an inert-gas atmosphere. Thorium can be soft-annealed after cold working (e.g., rolling) by heating to 500 – 700 °C. No problems occur due to phase transition since these occur only above 1400 °C. Impurities picked up during the various production processes affect workability. Small amounts of oxygen and beryllium have little effect, but carbon causes hardening. As with steel, considerable precipitation hardening occurs on quenching from the soft-annealed state at 600 – 800 °C (see Table 15). Elements that form carbides (e.g., titanium, niobium, and tantalum) considerably counteract this effect.

The dimensionally accurate tubes – required for fuel elements used in breeder reactors – were usually extruded at 600 – 700 °C, using a protective coating of copper or soft iron. Both of these metals form reaction zones with thorium that must subsequently be machined off. To prevent this, oxidic coatings on thorium were investigated. Alternatively thorium can also be pre-

heated in a molten salt bath consisting of nitrites and cyanides of alkali metals. The adherent salt film acts as a protective and lubricating film. The method eventually favored was to coextrude thorium with an inner and outer cladding of aluminum. Zirconium of similar plasticity obtained by preheating zirconium ingots was used as cladding at a later stage. Process details are unknown for reasons of military secrecy.

8. Intermetallic Compounds and Alloys

8.1. Thorium as the Main Component

Thorium has limited solubility in carbon and nitrogen, and can form compounds of metallic character with both elements. These are described below and in Chapter 5.

Alloys and compounds in which the alloying element vaporizes below the melting point of thorium cannot normally be produced. When the alloying elements have especially high melting points, impurities can be picked up from the crucible or electrode materials (e.g., W, Be, Zr, Cu, or C).

This discussion is limited to alloys and compounds that produce improvements in the properties of thorium, especially its corrosion resistance and strength and hardness properties.

8.1.1. Thorium and Carbon

Carbon is usually present as an impurity in thorium. Thorium produced by decomposition of thorium iodide contains 0.01 – 0.05 % C, and from halide reduction 0.03 – 0.12 % C. As mentioned in Chapter 7, carbon is one of the few elements that increases hardness and age hardening properties of thorium. Of all the elements that improve steel properties, only chromium can by itself (and even more in combination with carbon) produce comparable effects in thorium. Only indium seems to be more effective but is excluded from nuclear applications due to its neutron absorption. The other metals investigated (Ti, V, Mo) have a minor hardening effect, probably due to the formation of carbides with the carbon in thorium. However, the effect is partially negated by the hardness reduction caused by removal of carbon. The Th – C constitutional diagram (Fig. 20) shows the two compounds ThC and ThC_2 (see Chap. 5). The effect of temperature on the solubility of carbon in thorium is given below:

20 °C	0.35 wt %
800 °C	0.43 wt %
1018 °C	0.57 wt %
1215 °C	0.91 wt %

The hardening effect of carbon in the presence of chromium is shown in Table 16. (Chromium and thorium form a simple eutectic system without intermetallic compounds.) The hot forming property (>700 °C) of thorium is not negatively affected at a carbon content ≤0.4 wt %.

8.1.2. Thorium and Nitrogen

The compounds ThN and Th_2N_3 are described in Chapter 5. The solubility of nitrogen in thorium increases linearly with temperature, being 0.05 % at 850 °C and 0.35 % at 1500 °C.

Table 16. Mechanical properties of thorium – chromium – carbon alloys (arc melted, cold rolled about 85 % and annealed 30 min at 650 °C)

Figure 20. Phase diagram of the thorium – carbon system

Table 17. Mechanical properties of thorium – nitrogen alloys (hot rolled, cold rolled 50 % and annealed 2 h at 850 °C)

Nitrogen content, wt %	Yield strength (0.2 % offset), MPa	Tensile strength, MPa	Elongation (in 1 in.), %	Reduction of area, %	Hardness, VHN
Unalloyed	77.2	135.8	44	60	45
0.17	113.1	205.5	32	54	69
0.18	122.7	207.5	33	54	68
0.41	130.3	233.0	32	48	74

∗ Analyzed 0.012 wt % carbon and 0.08 wt % oxygen.
∗∗ VHN = Vickers hardness number.

In thorium formed by halide reduction, nitrogen is usually present only at levels of 0.02 wt %. The strength of thorium – nitrogen alloys increases moderately with increasing nitrogen content (see Table 17). Precipitation hardening (age hardening) of the alloy after annealing at 850 °C occurs only with quenching temperatures of $<$300 °C.

8.1.3. Thorium and Aluminum

In the thorium – aluminum system, six definite compounds are thought to exist. Of these, only $ThAl_3$ is well described. The solubility of aluminum in thorium is very low (0.6 – 0.7 wt %), so that alloys containing small amounts of aluminum are very brittle. The solubility of thorium

in aluminum is even lower. Alloys containing >10 % aluminum decompose rapidly in moist air, so that, unlike corresponding compounds of uranium and the higher actinides, they will probably not be used in nuclear technology.

8.1.4. Corrosion-Resistant Thorium Alloys

Small additions of alloying elements (to the extent permissible when thorium is used in nuclear technology) can give moderate improvements in resistance to corrosion by water. Improvements are obtained with carbon and beryllium at 100 °C and 200 °C, silicon at 100 °C, and titanium and zirconium at 200 °C. All other alloying element tested thus far have shown either no effect or harmful effects. The carbide formers are the most important of these.

8.1.5. Thorium Alloys Used in Thorium Production and Nuclear Applications

Thorium and Zinc. The thorium – zinc constitutional diagram (Fig. 21) shows four compounds with intermediate eutectics. With 30.5 atom % zinc, an alloy melting at only 1055 °C is formed. This is utilized in the thorium production process (see Chap. 6). However, high temperatures are required to drive off residual zinc.

Thorium and Beryllium. In casting operations with BeO crucibles, thorium picks up 0.02 –0.06 % Be as an impurity. However, beryllium, which has a high vapor pressure, can be driven off from the melt. The brittle compound $ThBe_{13}$ is formed in analogy to beryllium compounds of other actinides, and the eutectic containing 1.75 % Be melts at 1215 °C. Corrosion properties of thorium are improved only with low concentrations of beryllium.

Thorium and zirconium are mutually soluble in all proportions in the β-thorium region (≥1380 °C), and 1.5 wt % zirconium dissolves in thorium at 600 °C (Fig. 22). Zirconium concentrations of >80 wt % give good resistance to corrosion by water (hafnium behaves similarly to zirconium).

Thorium and Uranium. The constitutional diagram for the thorium – uranium system is shown in Figure 23. At the melting point of the eutectic (1270 °C), the solubility of uranium in α-thorium is only 2.5 atom %, while the solubility of thorium in uranium at 900 °C is only 0.3 atom %. Whereas all authors confirm the existence of two eutectics, they are in agreement on the size of the miscibility gap only between 6 and 49 atom % Th. High uranium contents harden thorium, and the addition of small amounts of carbon leads to work hardening. The solubility of uranium in thorium is adequate for the production of ^{233}U in a breeding process, but this is of little significance in the presence of fission products.

Figure 21. Phase diagram of the thorium – zinc system

Figure 22. Phase diagram of the thorium – zirconium system

Figure 23. Phase diagram of the thorium – uranium system

Thorium and Plutonium. The thorium – plutonium system has been investigated only at the plutonium-rich end, as shown in Figure 24. The region with high thorium content that is relevant to nuclear physics is so far unknown. Nothing is known about the effect of plutonium on the β-phase of thorium (>1400 °C). The compound Pu_2Th (orthorhombic, unit cell dimensions: $a = 0.982$ nm, $b = 0.8164$ nm, $c = 0.6681$ nm) forms a eutectic with plutonium at 7 atom % thorium, with a melting point of 615 °C.

Figure 24. Phase diagram of the thorium – plutonium system

8.2. Alloys Containing Low Concentrations of Thorium

Thorium in low concentrations can be used similarly to cerium mischmetal as a hardness and hot-strength improver in magnesium and Mg – Zn alloys [31] and in aluminum alloys, whose seawater resistance is also improved. The added thorium is precipitated at the grain boundaries in the form of intermetallic compounds. These cause grain growth, although this can be counteracted by small additions of zirconium.

Thorium was widely employed in light magnesium alloys used in automobile crankcases produced by pressure die casting, and provided work-hardening properties and increased hot strength and creep resistance. The principal alloys used were of the type Mg – Zn – Th – Zr, which contained 0.15 – 3 % thorium and up to 3 % zinc. More than 100 t of thorium was used for this application. Although thorium gives the required properties at lower levels than those required with mischmetal, the latter is preferred for cost reasons.

In general, small additions of thorium, like rare earth additions, increase the hot strength and antiscaling properties of many alloys. Such additions are therefore used in jet engines and in resistance heaters. The effect is due partly to deoxidation and partly to the formation of dense, adherent coatings of scale.

Copper and silver become much harder with small additions of thorium. These alloys are used to produce "nonstick" electrical contacts with long lifetimes. Copper – thorium alloys are also used as welding electrodes. An intermetallic compound of thorium with silver (Ag_5Th_3) is pyrophoric. Alloys of nickel with 3 % thorium form a good bond to ceramic bodies and are used for posts in dentistry [32].

Other intermetallic compounds with a promising future include $ThMn_{12}$ as a material for permanent magnets [33]. Compounds of the type $ThCr_2Si_2$ have been tested as superconductors [34].

9. Uses

9.1. Nuclear Technology [35]

Production of ^{233}U. Use of thorium in the nuclear industry is based on its ability to behave as a breeder. It absorbs neutrons and forms ^{233}U by successive release of two β-particles according to

$$^{232}_{90}\mathrm{Th} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{233}_{90}\mathrm{Th} \xrightarrow{\beta^-,\ 22.3\ \mathrm{min}}$$

$$^{233}_{91}\mathrm{Pa} \xrightarrow{\beta^-,\ 27.0\ \mathrm{d}} {}^{233}_{92}\mathrm{U}$$

The isotope ^{233}U is notable for the fact that the ratio of neutrons liberated on fission to those absorbed is more favorable than the corresponding ratio of ^{235}U and ^{239}Pu. This has aroused interest in this nuclide – which is complicated to produce – in both the military and the civil areas. The ^{233}U formed from thorium can either be separated from the breeder material by chemical methods or undergo fission in situ by absorption of further neutrons, thereby releasing energy. Both methods are subject to a number of limitations.

Chemical Separation of 233 U. In separating ^{233}U, it must be kept in mind that ^{232}U can be formed in an *n*,2*n* reaction with neutrons with an energy of >6.27 MeV from the ^{233}U already formed, and mainly from ^{232}Th via ^{231}Th and ^{231}Pa by further neutron capture. To avoid this reaction, thorium must be allowed to interact only with low-energy thermal neutrons. The same isotope ^{232}U is also formed with a cross section 14 times as large by low-energy neutron capture by ^{230}Th. Although ^{230}Th is present in thorium at a level of only a few parts per million, its concentration can be higher if thorium is a byproduct of uranium production, in which case ^{230}Th is present as an α-decay daughter of ^{234}U.

Whereas ^{232}U is not itself harmful, a serious handling problem arises from the fact that it decays relatively rapidly to its daughter product ^{208}Tl, which emits penetrating γ-radiation with an energy of 2.62 MeV.

In practice, this means that thorium must not be used in a thermal neutron flux in molecular proximity to neutron sources (e.g., as a U – Th alloy, mixed oxide, or mixed carbide) – which would give optimum neutron capture – but should be kept separate from the neutron source ^{235}U (or ^{239}Pu) in breeder rods covered with a layer of moderator.

To give an idea of quantities, if 1 t of thorium is irradiated for some weeks in the carefully thermalized neutron flux and then cooled for 150 d to enable the fission product iodine, which interferes with the separation process, to decay, this forms ca. 1 kg ^{233}U containing ca. 8 mg/kg ^{232}U. This then remains in a handleable state for some weeks without complicated gamma shielding. The overall complexity of this operation can be reduced by replacing the thorium metal rods with ceramic ThO_2 tablets, which are easier to produce but more difficult to dissolve later since $HF + HNO_3$ must be used. Even under these conditions, with a handling concentration limit of 10 – 20 mg/kg ^{232}U, an optimistic price estimate for ^{233}U is still twice that of highly enriched uranium [36]. According to published data, no more than 3 t ^{233}U has been produced worldwide, of which ≤ 800 kg in the United States. New fuel rods have been produced from this in only one full-scale experiment (Kilorod Facility, Oak Ridge, Tennessee [37]).

Attempts to irradiate thorium in the form of a fluid medium or of ThF_4 dissolved in fused salts [38] were finally not successful.

"In Situ" Fission. In an alternative method, ^{233}U is caused to undergo fission with generation of heat at the place where it is formed. Here, fewer possibilities exist for controlling the nuclear reaction, and thorium is by no means completely consumed, but the system is technically easier to realize. Also, a particular property of thorium can be utilized – i.e., its ability to form a series of solid solutions with other actinide oxides (UO_2, PuO_2) – thereby stabilizing them at high temperature. This is mainly a property of ThO_2, to a lesser extent of the carbide, and to a small extent of the metal. Also, since the formation of ^{232}U does not present a problem, the higher neutron flux (by at least an order of magnitude) of the fast breeder reactor is advantageous.

Thorium oxide forms a series of mixed crystals with a cubic fluorite structure with both UO_2 and PuO_2, so that fuel elements can be produced in which thorium is the main component and which are stable when heated in air to >1200 °C. This facilitates both production and safety analysis. The mixed crystals show no phase transformation up to their melting point of >2600 °C. However, used fuel elements of this type can be dissolved only in mixtures of HNO_3 and HF, which attack most available containment materials. Except in India where much thorium but comparatively little uranium is available, all fast breeder programs currently in operation are based on the uranium – plutonium cycle, and no thorium is used.

Thorium could be used in thermal reactors to extend the use of ^{239}Pu, which is produced as a fuel by transformation of ^{238}U. However, continuous hydrogenation of the cladding material (Zircaloy) limits the burnup in water reactors to

ca. 50 000 MW · d/t, so that there is little advantage in using thorium, which is therefore limited to *graphite-moderated thorium high-temperature reactors* (THTRs), which allow ten times the burnup. Here, the fuel elements consist of small particles of uranium and thorium oxide or uranium and thorium carbide, embedded in a graphite matrix. For more details see → Nuclear Technology, Chap. 3.2., → Nuclear Technology, Chap. 5.3.2.; [39].

Owing to parasitic neutron capture in the thorium cycle, Th – U fuel required highly enriched uranium (93 % ^{235}U), and the possible consequent proliferation of weapons-grade material led to concern on the part of source countries (United States). Therefore, new fuel variations are no longer based on thorium. Slightly enriched uranium (10 % ^{235}U), which is not suitable for weapons, is used instead.

So far, high-temperature reactors have not reached the threshold of economic viability achieved by other methods of generating electricity. The safety advantage has not compensated for this disadvantage, and no power stations of this type are currently under construction or being operated.

Because of the wide variations in targeted burnups and the question of whether – and to what extent – thorium is recycled to the reactor, figures for thorium consumption fluctuate not only with reactor capacity but also according to the mode of operation. In using the minimum consumption figures that correspond to maximum recycling, the THTR reactor requires 7.3 t/a thorium for each 1000-MW_e capacity, 340 kg ^{233}U can be recovered from the used fuel elements, and 6.8 t Th (containing isotopes that interfere with a second burnup) must be disposed of as nuclear waste. The initial inventory of the reactor is ca. 60 t of thorium.

9.2. Conventional Applications

9.2.1. Illuminants

The most important application of thorium followed the discovery by Auer Von Welsbach in 1892 that some rare earth oxides and thorium oxide, when introduced in the form of woven yarn into a gas flame, considerably increased the luminous efficacy of the flame. This emission of light is excited by cathode rays, heat, and UV radiation. Although pure cerium oxide converts the UV fraction of an oxidizing gas flame into visible light more efficiently than ThO_2, it is not used in practice because so much light is emitted in the IR region that "cooling" of the gas flame occurs. Excitation of cerium oxide gives a gas flame temperature of only 1500 °C, whereas thorium oxide gives 1930 °C. Maximum luminous efficacy occurs with 1 % cerium oxide in ThO_2 [40].

The requirements of maximum light-emitting surface area together with stability in a gas flame in which high flow rates occur at the zone of maximum temperature led to the development of the gas mantle, whose shape matches that of the combustion zone of the flame. Today, commercially available gas mantles are produced by soaking artificial silk (viscose or cellulose ester fibers) in a solution of thorium and cerium nitrates. The hydroxides are then formed by treatment with alkali and fixed to the fiber; the organic carrier material is burned off, and the remaining ash structure is fixed with collodion lacquer.

Modern gas mantles give a luminous efficacy of 3 lm/W with propane, which is even better than that produced by electric incandescent lamps. Gas mantles are expressly excluded from the restrictions on radioactive substances, although the inhalation of ash from used gas mantles, which can easily occur on careless handling, can lead to harmful deposits in the lungs.

Thorium oxide also had limited application as a light converter (UV into visible light) in fluorescent lamps before modern oxide mixtures were developed.

9.2.2. Electron Emitters

In the production of incandescent filaments, the rate of recrystallization of tungsten is considerably reduced by adding 1 % ThO_2 to the tungsten sintering powder before drawing the filaments.

A side effect of this addition was noticed: i.e., that a small addition of thorium oxide to the tungsten used in heated electrodes considerably reduces the work function of electrons (see Fig. 4) [41]. This is probably due to the formation of a ThO dipole layer, which is constantly renewed from the interior of the elec-

trode. Therefore, since 1922, thoriated tungsten wires have been used in electronic tubes and in the cathodes and anticathodes of X-ray tubes and rectifiers. Owing to the reactivity of thorium with O_2 and N_2, italso acts as a getter for impurities in the evacuated tubes.

These applications decreased very much following the introduction of transistors in the 1950s, but reduction of the electron work function is still a useful phenomenon, having a beneficial effect on the process of welding in an inert gas (argon, helium), for which thoriated tungsten electrodes are used.

9.2.3. Ceramics and Glass

Thorium oxide crucibles represent the most refractory material known and can be used for melting pure, carbon-sensitive metals at 2300 °C. The crucibles are produced by sintering fused and ground thorium oxide – small additions of ZrO_2, P_2O_5, and cryolite being used as sintering aids. Although its application is very limited, ThO_2 is also used to increase the density of ZrO_2 crucibles.

Like ZrO_2, ThO_2 increases the hardness of dispersion-hardened alloys, e.g., in an Ni – 16 Cr – (3 – 5)Al alloy for gas turbine blades.

The addition of ThO_2 to glass leads to extremely high refractive indices with low dispersions and densities lower than those of lead glass. However, this application is also limited because rare-earth oxides have a similar effect and are not α-emitters.

9.2.4. Catalysts [42]

The catalytic effect of ThO_2 seems to be due to an increase in the mobility of hydroxyl ions and hydrogen. Thus, a large number of hydroxylations, hydrogen additions, hydrogen eliminations, oxidations, and reductions have been documented in which thorium catalysts are used. The earliest use of thorium as a reactant and catalyst at the same time was the reaction of aliphatic dicarboxylic acids to give ring ketones (civetone, synthetic musk) by dry distillation of thorium salts [43].

Thorium oxide was used as a fixed-bed catalyst with nickel and cobalt on a kieselguhr carrier, first in ammonia synthesis and then in oil refining and the Fischer – Tropsch process. It was also employed in dehydrogenation, isomerization, and a number of other reactions.

An alloy of platinum with 10 % thorium is a very good catalyst for the oxidation of ammonia to nitrogen oxides. However, a 5 % rhodium alloy with platinum is now preferred because of its superior mechanical properties and longer lifetime in the form of a gauze.

In almost all cases, ThO_2 has been replaced by cheaper catalysts (e.g., based on rare earths) and is now hardly used.

9.2.5. Medicine

Thorium dioxide was used as a contrast medium (Thorotrast) when making X-ray photographs of hollow organs but has been replaced by nonirradiating substances.

^{225}Ra has been used experimentally for therapeutic irradiation, as this is the only isotope of radium that does not have a gaseous decay product. It is obtained either as a short-lived daughter nuclide of ^{229}Th, which is the most stable daughter nuclide (half-life 7340 a) in the ^{233}U decay chain, or can be produced by neutron irradiation of ^{226}Ra.

9.2.6. The Demand for Thorium

In the first phase of utilization from 1893 to 1940, mostly for the production of gas mantles, worldwide consumption was ca. 8000 t ThO_2, of which 3300 t came from India, 4000 t from Brazil, 370 t from the United States, 100 t from Indonesia, 60 t from Sri Lanka, and the rest from Norway, Australia, and a few other countries, together with a small amount of recycled material.

India, which produced 280 ± 40 t/a between 1940 and 1954, has not published any figures since development of the nuclear application.

Nonnuclear use has in general decreased since 1950 [44].

In Germany in the 1990s, thorium consumption decreased to ca. 1.5 t/a, having been 3 – 5 t/a a few years before. Four companies produce thoriated tungsten electrodes, and one company produces electric discharge lamps. Gas mantles are mainly imported from France. Large quantities of thorium oxide, a coupled product from

rare earth production, are stored in various parts of the former German Democratic Republic. This material will probably not be utilized but will be deposited as radioactive waste in a waste disposal site.

10. Product Quality and Analytical Methods

Product Quality. Thorium is commonly marketed in the form of solid thorium nitrate. Here, the thorium content and the level of certain impurities are important. Rare earths, magnesium, calcium, and heavy metals that can be precipitated by sulfide (mainly Fe) are determined.

Thorium nitrate used in the production of gas mantles is highly purified by multiple recrystallization or oxalate precipitation. Rare earths (except in concentrations $<1\,\%$) are undesirable because they stimulate the emission of IR radiation, thereby reducing the emission of visible light. Very small proportions ($>0.02\,\%$) of SiO_2 lead to embrittlement of the gas mantle [45].

Sulfate in ThO_2 has a detrimental effect on crucible production and is removed by multiple dissolutions and precipitations of thorium as oxalate.

The rare earths are also undesirable in nuclear technology because some of them (e.g., erbium and gadolinium) are strong neutron absorbers. Therefore, these elements must be removed. If thorium is used in metallic form, the oxygen and carbon contents are important, the latter from the point of view of hardness properties. When processing irradiated thorium, uranium and thorium must be separated.

The determination of low concentrations of thorium is important in the quality control of alloys. Very low concentrations must be determined in geochemistry and environmental analysis, and when removing ^{230}Th from uranium compounds.

Analytical methods are based on the selective separation of thorium. The natural accompanying elements and compounds in thorium include La and lanthanides, Y, Sc,Ti, Zr, Hf, U, Fe, Al, Ca, SiO_2, and P_2O_5. Only a few reactions exist that are specific for thorium; moreover, it has a stable valence of four so redox separations are impossible. The most difficult precipitation separation is that of scandium, although large amounts of this element are seldom associated with thorium.

Precipitation processes usually start with solutions in relatively strong mineral acids. Precipitation of thorium as the oxalate, fluoride, peroxide, iodate, and hypophosphate gives the best selectivity, the last of these even against rare earths. Some organic dicarboxylic acids, especially tetrachlorophthalic acid, are more selective than oxalic acid. Dimethyl oxalate, which slowly hydrolyzes in warm solutions of mineral acids, can also be used to give slow formation of a precipitate that is free of inclusions.

Most of the compounds soluble in organic solvents that are used for *liquid–liquid extractions* in nuclear technology have been tested for the selective separation of thorium, mainly from solutions in nitric acid, for analytical purposes. They include 1-(2-thenoyl-3,3,3-trifluoroacetone (TTA), mesityl oxide, dibutoxytetraethylene glycol ("penta ether"), long-chain amines (trilaurylamine), TBP [46], and a series of organic phosphonium compounds, especially bis(dialkylphosphinyl)methane [47]. The latter extractants, in particular, separate uranium and thorium selectively from the rare earths. Uranium is most effectively separated from thorium by means of the appropriate choice of ligands (branched or straight-chain) and of the concentrations of the acid and salt in aqueous stripping. Bis(dialkylphosphinyl)-methanes are more selective extractants than trialkylphosphine oxides. The branched-chain, sterically hindered phosphine oxides extract U(VI) more effectively, whereas the straight-chain compounds extract thorium more effectively.

Good selectivity against the rare earths and selectivity against uranium can also be obtained by extracting thorium with TBP from nitric acid solution if the TBP concentration is 40 % in the organic solution (instead of 10 % as used with uranium). In contrast to uranium, stripping is best carried out by salting out with nitrates in the presence of moderately concentrated HNO_3.

Few selective *analytical reagents* for thorium in solution are known. Their selectivity is generally considered to depend on the bond formed with inner electrons of thorium, as in the case of precipitation with dicarboxylic acids. The

compounds formed are generally more sparingly soluble than the corresponding rare earth compounds.

Reagents include a series of weak organic acids with acid groups on adjacent carbon atoms, and other compounds that can form chelate-like complexes. The pink coloration produced by the reaction of ammoniacal solutions of pyrogallol with Th^{4+} has been known for some time, although this is only moderately stable and selective. The formation of star-shaped groups of red needles with Orange II (*p*-(2-hydroxy-1-naphthyl)azo]benzenesulfonic acid), is used for microchemical detection. The most selective reaction known is the formation of a red coloration with thorin, 4-(2-arsonophenylazo)-3-hydroxy-2,7-naphthalenedisulfonic acid [*3688-92-4*] (in the absence of oxalate and fluoride). This coloration is measured at 54.5 nm in sulfuric acid solution, although a number of other compounds that react in a similar way (dibenzoylmethane, aurintricarboxylic acid, alizarin S) also give color reactions or form color lakes.

When impurities originating from production and processing of thorium metal and its compounds are to be analyzed most of the thorium must be separated first. The impurities can then be determined by the usual methods. This applies also to spectrographic analysis, for which most of the thorium should first be removed because of its complex line spectrum.

11. Toxicology

Thorium, its natural decay products, and its compounds are toxic both as heavy metals and as radioactive substances. However, their heavy-metal toxicity is low because of their low solubility in body fluids and organs, and has been compared with that of aluminum.

12. Industrial Safety

In addition to toxicological risks, the spontaneous flammability of thorium metal constitutes a handling hazard.

Thorium has been extracted and processed on an industrial scale since 1893, mostly as the oxide. However, the incidence of harmful effects associated with the handling of thorium is very low. In the absence of strong complex formers (e.g., citrates), water-soluble thorium compounds are immobilized close to the point of incorporation into the body in the form of insoluble hydroxides. Animal experiments first gave an LD_{50} of 1 – 2 g/kg. The low water solubility also prolongs the excretion process, mainly via the feces, and to a lesser extent the kidneys. Exposure to thorium occurs mainly by inhalation of dust into the tracheobronchial tract and the lungs. No toxic chemical effect has thus far been observed in these areas, but radiation damage can occur in the lungs and from the small amounts of thorium transported to the bones.

Thorium is often compared with uranium, which has been well investigated radiologically. Thorium differs from uranium in the more rapid buildup of its daughter nuclides, which also have chemically different properties (Fig. 1). Important daughter nuclides are ^{228}Ra, ^{228}Ac, ^{228}Th, ^{224}Ra, and ^{220}Rn. Other decay products are of little radiological importance. As shown in Figure 2, freshly separated thorium passes through two activity maxima, one after ca. 5 weeks and a second after ca. 60 a, with an intermediate activity decrease after 3 a. In addition to the relatively low β- and γ-radiation, α-radiation has a significant effect on the living organism due to the high ionization density that it produces. During chemical isolation of thorium from ores or residues that have been stored for a long time, ^{228}Ra and ^{224}Ra become concentrated in the filtrate (to>70 % in oxalate precipitation). These nuclides are precipitated with sulfate to concentrate them in sediment and prevent them from passing into receiving waters. Furthermore, phase transformations and chemical changes of thorium and its compounds cause the release of all the ^{220}Rn formed in the solid up to that point, which can lead to the buildup of significant α-activity in poorly ventilated areas. Table 18 gives the maximum permissible concentrations of thorium and its decay products according to the USAEC Regulations of 1955 (still in curies). The German legal requirements for thorium according to the Strahlenschutzverordnung are listed in Table 19. The recommended annual limits for incorporation (ALI) in the International Commission on Radiological Protection (ICRP) 30 Regulations are based on a metabolic inhalation model. This has been used to test the relationship between the uptake of tho-

Table 18. Maximum permissible concentrations of thorium and the thorium daughter products radium-228 and radium-224

Element	Body limit, μC	Water MPC $*$, μC/cm^3	Air MPC $*$, μC/cm^3

rium and biological detection in a large group of workers in a monazite processing plant [48]. It showed that the analysis of urine and feces correlated only moderately well with the short-term uptake of thorium. After inhalation of insoluble thorium compounds urine analyses showed a maximum thorium uptake fraction of 1.4×10^{-3}, up to 12 % were found in feces, both at the second day after incorporation. Almost all measurements yielded higher figures than the ICRP recommendation, although there was no detectable damage to health. Cytogenetic studies in parallel with this showed no correlation between the frequency of chromosomal aberrations and the duration of contact. Clearance from the lungs has a biological half-life of>500 d, and from bones ca. 200 a.

The workplace should therefore be kept as dust free as possible.

13. Environmental Protection

Thorium occurs almost ubiquitously in nature in low concentrations. Because of its poor solubility in water, it occurs in extremely low concentrations in the biological cycle, and because its use in industry is not increasing, special environmental protection measures are unnecessary. Only in a few locations where thorium was used or processed in the past are soil remediation operations occasionally required.

14. Legal Aspects

According to German atomic law (AtG), thorium that has not been irradiated is a "miscellaneous radioactive material" but is not a "nuclear fuel" so that according to §3/§9 AtG it must be safely disposed of as a radioactive material. According to the nuclear nonproliferation treaty, thorium is classed as a controlled substance. Quantities of 20 t (source material) must be checked at least once per year, as also prescribed for Europe by Euratom Regulation no. 3227/76. Persons constructing and operating plants for the production, separation, utilization, and storage of thorium must report kilogram or higher quantities of thorium.

Exceptions to this duty to report include gas mantles, to which the limits imposed by the radiation protection regulations do not apply, although the amount of freshly purified thorium in a gas mantle represents the maximum permitted intake of activity for 100 person-years. Aged thorium contained in gas mantles could represent ten times this amount.

Abbreviations:

BTU	benzylthiouracil
CBZ	carbimazole
DIT	diiodotyrosine
INN	International nonproprietary name
MIT	monoiodotyrosine
MMI	methimazole, thiamazole
MTU	methylthiouracil
PTU	propylthiouracil
rT_3	reverse L-triiodothyronine
T_3	L-3,5,3′-triiodothyronine, liothyronine
T_4	L-thyroxine, L-3,5,3′,5′-tetraiodothyronine
TBA	thyroxine binding albumin
TBG	thyroxine binding globulin
TBP	thyroxine binding protein
TBPA	thyroxine binding prealbumin
Tg	thyroglobulin
TRH	thyrotropin releasing hormone
TRIAC	triiodothyroacetic acid
TSH	thryroid-stimulating hormone
TSI	thyroid-stimulating immunoglobulins

1. Introduction

Thyrotherapeutic agents are drugs that affect the function and growth of the thyroid gland. The interest in this class of substances is due to the commonness of diseases of the thyroid. For example, 15 % of the German population suffer from enlargement of the thyroid gland (goiter) [1].

The thyroid is an endocrine gland which provides the organism with the metabolic hormones L-thyroxine (T_4) and L-triiodothyronine (T_3). In terms of weight, the largest component of the thyroid hormones T_4 and T_3 is the element iodine. Iodine is taken in as iodide in food, resorbed, and actively transported into the thyroid gland, where it is used for the synthesis of the thyroid hormones. The adult human organism requires an iodine supply of 150 – 300 µg/d for sufficient synthesis of thyroid hormones [1].

The synthesis of thyroid hormones involves several steps: iodide entry into the thyroid gland (iodination) and oxidation to I_2, incorporation of iodine into tyrosine with the formation of MIT and DIT (iodization), and the coupling of iodotyrosines to form iodothyronines. Iodization and coupling occur in thyroglobulin (Tg). This is followed by the storage phase in Tg and the incretion phase (secretion of the thyroid hormones into the bloodstream). Depending on the requirements of the organism, the thyroid gland releases its hormones into the bloodstream, regulated by hypothalamic TRH and hypophysial TSH.

About ten times more T_4 than T_3 is produced and released into the bloodstream. Outside the thyroid gland, T_4 is mostly deiodinated in the peripheral tissue to T_3, which is 100 times more active, and partly to rT_3, which is inactive. Serum levels of the thyroid hormones that are too high result in suppression of TSH secretion in the hypophysis, while serum T_4 and T_3 levels that are too low lead to stimulation of TSH secretion.

This feedback mechanism guarantees the maintenance of a constant level of thyroid hormone and, consequently, normal metabolism.

Diseases of the thyroid are classified according to functional and morphological criteria. From a functional standpoint, a distinction is made between hypofunction (hypothyreosis) and hyperfunction (hyperthyreosis). Morphological classification includes diffuse struma, multinodular struma, thyroiditis, Morbus Basedow, thyroid cysts, adenoma, and malignant tumors.

Hyperthyreosis is characterized by an increased peripheral blood level of thyroid hormones. The resulting complaints include insomnia, weight loss, diarrhoea, tachycardia and, in severe cases, central nervous disorders.

Diseases of the thyroid that can be connected to hyperfunction are: Morbus Basedow, functional autonomy, thyroiditis, and secondary hyperthyreosis in the case of pathologically increased hypophysial TSH incretion.

Hypothyreosis is characterized by decreased hormone levels in the blood. The resulting complaints include increase in weight, obstipation, bradycardia, central nervous disorders, depression, sensitivity to cold, myxedema, and cretinism. Hypothyreosis can be congenital due to organ dysgenesis and disturbances of hormone synthesis and can appear in the course of a thyropathy or as a result of medication, radiation therapy, or surgical treatment. The most frequent cause of acquired hypothyreosis is autoimmune atrophy.

Thyroid hyper- and hypofunction can be rectified by the administration of the appropriate preparations.

2. Thyroid Hormones as Therapeutic Agents

2.1. Pharmacology of the Thyroid Hormones (→ Hormones, Chap. 2.1.1.).

Thyroid hormone preparations find therapeutic application for:

1) Substitution in the case of hypothyreosis of any genesis
2) Preventive treatment against recurrence of struma after strumectomy or radioiodine treatment
3) Suppressive treatment of euthyroid struma
4) Substitution therapy after thyroidectomy and radioiodine treatment for thyroid malignancies
5) Treatment accompanying thyroid depressant therapy for hyperthyreosis

Four types of preparations are available for medicamentous therapy [2]:

1) Levothyroxine preparations (T_4)
2) Liothyronine preparations (T_3)
3) Preparations that combine T_3 and T_4
4) Preparations that combine T_4 and iodide

T_4 and T_3 differ fundamentally in their pharmacokinetic properties, as shown in Table 1. Today, monotherapy with T_4 is preferred to treatment with T_3 or combined treatment with T_4 and T_3. In this way a demand-orientated supply

Table 1. Pharmacokinetic data of the hormones T_4 and T_3 (active hormone)

	Levothyroxine T_4	Liothyronine T_3
Incretion rate [25]	94 – 110 µg/d (120 – 140 nmol/d)	16 – 22 µg/d (24.6 – 33.8 nmol/d)
Utilization rate [25]	80 µg/d (102 nmol/d)	60 µg/d (92 nmol/d)
Blood level [26]	60 – 80 µg/L (75 – 105 nmol/L)	1.0 – 1.5 ng/L (1.5 – 2.3 nmol/L)
Unbound physiologically active form [26]	0.03 – 0.05 %	0.3 – 0.5 %
Plasma protein binding [25]	99.9 % [a]	99.7 % [b]
Dosage	50 – 300 µg	10 – 100 µg
Relative activity [c]	1	4
Enteral resorption [d]	75 – 85 %	78 – 95 %
Bioavailability	75 – 85 %	80 – 95 %
Distribution volume [25]	12 L	46 L
Total metabolic clearance rate [25]	1.17 L/d	26.1 L/d
Plasma half-life	6 – 7 d	1 d
Onset of action	3 – 5 d (oral), 6 h (i.v.)	12 – 48 h
Maximal effect after	ca. 9 d (single dose)	ca. 2 – 3 h (single dose)
Duration of effect	7 – 10 d	3 – 5 d
Plasma transfer	slow	slow
Excretion in breast milk	in small amounts	in small amounts
Biliary excretion	yes	yes
Enterohepatic circulation	yes	yes
Renal unchanged	0 %	0 %

[a] Up to 80 % on TBG, up to 15 % on TBPA, up to 10 % on TBA.
[b] Up to 99.7 % on TBG, up to 0.3 % on TBPA and TBA; binding is ten times weaker than T_4.
[c] For enteral administration.
[d] In fasting state; ingestion of food lowers resorption to 35 %.

of the metabolically active T_3 is guaranteed to a certain extent. The biological half-life of T_4 of 6 – 7 d is much longer than that of T_3 (ca. 19 h). T_4 is converted extrathyroidally to metabolically active T_3. Thus, even a single dose of T_4 results in essentially constant hormone levels in the serum. Monotherapy with T_3 can easily result in unphysiological T_3 peak values in the serum and overdosage symptoms. Therefore, treatment with T_3 offers no advantages over T_4 therapy. An exception is the short-term application of T_3 if thyroid hormone therapy must be interrupted prior to diagnostic and therapeutic measures.

Combined treatment with both thyroid hormones attempts to imitate physiological conditions. The balanced combination of both thyroid hormones (T_4 : T_3 = 5:1 or 10:1) should guarantee physiologically adequate substitution and suppression.

Combination preparations are indicated when conversion to T_3 does not occur in the case of monotherapy with T_4. These preparations are used to treat struma caused by lack of conversion. Preparations that combine levothyroxine and iodide are given preference in the treatment of iodine-deficiency struma.

An adequate supply of iodide is required for protection against iodine-deficiency struma. Since in many areas of Germany, the alimentary supply of iodine is less than the iodine requirement and endemic iodine deficiency affects both the function and morphology of the thyroid gland [2] (formation of struma, degeneration, autonomy), adequate prevention of iodine deficiency by administration of iodide preparations is recommended (100 – 200 µg I^-/d).

As a rule, substitution therapy with thyroid hormones starts very slowly. The dosage is established individually, depending on the age, condition, and indication, the regular determination of the hormone values in the serum being imperative. If the dosage is correct, no undesirable effects occur. If the individual tolerance limit or the proper dose is exceeded, the clinical symptoms typical of hyperthyreosis can occur, especially if the dose is increased too fast at the start of treatment.

During pregnancy, substitution treatment for hypothyreosis of the mother should be rigorously carried out because otherwise the insufficient hormone production in the mother can result in defective development of the child. However, overdosage must be carefully avoided. Even in the case of high-dose therapy, the amount of thyroid hormones secreted into the breast milk during lactation is not sufficient for the development of hyperthyreosis or suppression of TSH secretion in the infant.-,10

2.2. Chemical and Physical Properties of Thyroid Hormones

Levothyroxine (INN), T_4, L-thyroxine, L-3,5,3′,5′-tetraiodothyronine, L-3-[4-(4-hydroxy-3,5-diiodophenoxy)-3,5-diiodophenyl]-alanine (IUPAC) [*51-48-9*], $C_{15}H_{11}I_4NO_4$, M_r 776.93, decomp. 235 – 236 °C, $[\alpha]_D^{20}$ +4.4° (3 % solution in 0.13 N NaOH in 70 % ethanol). Colorless, light-sensitive crystals, insoluble in water, ether, ethanol, and chloroform.

Levothyroxine sodium (INN), L-3-[4-(4-hydroxy-3,5-diiodophenoxy)-3,5-diiodophenyl]alanine sodium (IUPAC) [*55-03-8*], $C_{15}H_{10}I_4NNaO_4$, M_r 798.85.

Levothyroxine sodium *x*-water (INN) [*25416-65-3*], $C_{15}H_{10}I_4NNaO_4 \cdot x\,H_2O$, pH 8.9 (saturated, aqueous solution). White to lightly colored, light-sensitive, crystalline powder. Solubility: very sligthly soluble in water (solubility decreases with pH), slightly soluble in ethanol, insoluble in acetone, chloroform, ether, and soluble in alkali metal hydroxide solution. The analytical profile and synthesis of levothyroxine compounds are described in [3].

Liothyronine (INN), T_3, 3,5,3′-triiodothyronine, L-3-[4-(4-hydroxy-3-iodophenoxy)-3,5-diiodophenyl]alanine (IUPAC), [*6893-02-3*], $C_{15}H_{12}I_3NO_4$, M_r 651.01, *mp* 233 – 234 °C, $[\alpha]_D^{29,5}$ +21° (4.75 % solution in 1:2 1 M HCl/ethanol, pK_a 8.5, insoluble in water and ethanol, soluble in dilute alkali.

Liothyronine sodium (INN) [*55-06-1*], $C_{15}H_{11}I_3NNaO_4$, M_r 672.99, UV_{max} 319 nm. White to slightly colored powder, insoluble in water and ether, slightly soluble in ethanol, soluble in dilute alkali metal hydroxide solution. For synthesis, see → Hormones, Chap. 2.1.3.

Tiratricol (INN), TRIAC, TA3, 3,5,3′-triiodothyroacetic acid, 4-(4-hydroxy-3-iodophenoxy)-3,5-diiodophenylacetic acid (IUPAC) [*51-24-1*], $C_{14}H_9I_3O_4$, M_r 621.95, *mp* 65 °C from methanol and water; after recrystallization at 110 °C: 180 – 183 °C. Synthesis is described in [4].

TRIAC [5,6] is a natural metabolite of T_3. In spite of its high affinity for the T_3 receptor, TRIAC evidently has no physiological role. In vivo, it exerts a strong, dose-dependent and reversible inhibitory effect on the hypophysial secretion of TSH. The effects on peripheral tissue are negligibly small. Consequently, TRIAC has been used as an alternative to T_4 for hypophysial TSH suppression in patients suffering from thyroid carcinoma. More recent studies show that TRIAC results in increased L-thyroxine activity, even in peripheral tissue.

l-3,5-Diiodothyronine (INN), T_2, L-3-[4-(4-hydroxyphenoxy)-3,5-diiodophenyl]alanine (IUPAC) [*1041-01-6*], $C_{15}H_{13}I_2NO_4$, M_r 525.10, *mp* 256 – 257 °C (decomp.), $[\alpha]_D^{25}$ +25.2° [5 % solution in 1 M HCl:95 % ethanol (1:2)], colorless crystals. Thyroid hormone with a L-thyroxine-like activity. For synthesis, see [7].

3. Thyroid Depressants as Therapeutic Agents

Thyroid depressants are divided into five groups, based on their mechanism of action.

1) Iodination inhibitors, which inhibit iodide transport into the thyroid gland
2) Iodization inhibitors, which directly inhibit the synthesis of thyroid hormones
3) Inhibitors of hormone incretion
4) Inhibitors of T_4 and T_3 conversion
5) Radioiodine, which can destroy thyroid tissue by means of ionizing radiation

3.1. Iodination Inhibitors

Iodination inhibitors act as thyroid depressants by competitively inhibiting the uptake of iodine by the thyroid cell (iodination). They release accumulated iodide from the thyroid gland provided it is not incorporated into Tg molecules. In this manner, these agents inhibit the synthesis of the thyroid hormones, resulting in iodine depletion.

Iodination inhibitors are administered to block the thyroid gland prior to scintigraphic investigations of other organs with iodine isotopes, during the unavoidable application of iodine-containing contrast medium if an autonomic thyropathy is known to exist, and in the treatment of hyperthyreosis if other thyroid depressants must be discontinued due to unjustifiable side effects. These agents should not be used if treatment with radioiodine or iodine is to be performed. Perchlorate finds therapeutic application in the form of the sodium or potassium salt in a dosage of up to 1500 mg/d. The undesirable effects observed are gastrointestinal disturbances; serious but more seldom side effects are agranulocytosis, aplastic anemia, and nephrotic syndrome.

3.2. Iodization Inhibitors

Iodization inhibitors are derivatives of thiourea. Agents that are therapeutically used are: benzylthiouracil (BTU), methylthiouracil (MTU), propylthiouracil (PTU), carbimazole (CBZ), methimazole (MMI), and thibenzazoline. Today, CBZ and MMI have gained acceptance in the clinical practice [8].

These substances inhibit the iodine oxidation reaction catalyzed by a thyroid peroxidase [9], the incorporation of iodine into tyrosine, and the

coupling of tyrosine molecules to form iodothyronines. Thus, they inhibit the synthesis of thyroid hormones. This makes possible the symptomatic treatment of thyroid hyperfunction irrespective of its etiology.

In addition, thiourea derivatives are attributed with a favorable effect on the immunopathogenesis of hyperthyreosis [10]. At present, it cannot be definitely established to what extent the underlying immunopathogenetic process can be suppressed.

Processes that are not influenced are the transport of iodide into the thyroid gland, the incretion of the thyroid hormones, and hyperthyreosis due to hormone liberation after destruction of the thyroid cells (e.g., after radioiodine therapy or thyroiditis). This mechanism of action explains why the clinical effect starts only after the hormone depots in the gland have been emptied and the peripheral hormone concentrations decrease. An additional mechanism of action being discussed for PTU is the blocking of the peripheral deiodination of T_4 to T_3.

Indications for the administration of thiourea thyroid depressants include:

1) Initial and long-term treatment of Basedow hyperthyreosis
2) Initial treatment of thyroid autonomy
3) Treatment of transitory hyperthyreosis caused by inflammation
4) Intravenous treatment of thyrotoxic crisis (preferably PTU)
5) Intermediate therapy after radioiodine treatment until an euthyroid metabolic condition is reached
6) Preoperative and prior to radioiodine therapy in all hyperthyreosis conditions because treatment must always be given in the euthyroid state
7) Not for the treatment of hyperthyreosis caused by inflammation

Due to their goitrogenic action when given over an extended time period, antithyroid substances can be administered in combination with synthetic thyroid hormones.

In principle, all thyroid depressants give rise to the same undesirable effects. The total rate of side effects is about 14.3 % [11]. The most frequent are skin reactions (5.6 %) and ailments of the joints (1.6 %). The most dangerous side effect, which occurs with a frequency of up to 1 %, is toxic bone marrow damage (agranulocytosis, leukopenia, thrombopenia). Other rare side effects include gastrointestinal complaints, swelling of the joints, fever, headache, and rash.

The frequency of side effects varies greatly from agent to agent. CBZ, MMI, and PTU are favorably assessed. As a result of the lower dosage and toxicity, thioimidazoles are preferred to PTU, and MMI as an active metabolite to CBZ.

The highest rate of side effects is shown by MTU (14 %; agranulocytosis in 1 – 3 % of all cases). Hence, the use of MTU in ready-for-use drugs is no longer recommended [12].

Care must be taken during pregnancy because the drugs pass the placental barrier and can result in the development of struma or cretinism in the child. For this reason, during pregnancy, the lowest possible doses of thyroid depressants must be administered without the addition of thyroid hormones, which pass the placental barrier. In the case of combination therapy with a thyroid depressant and T_4, in spite of the euthyroid metabolic state of the mother, there is a risk of the development of hypothyreosis in the child due to thyroid suppression.

The agent of choice during pregnancy and lactation is PTU in the United States, and MMI in Germany.

A survey of the pharmacokinetic data of antithyroid agents is presented in Table 2 (see next page).

3.3. Inhibitors of Hormone Incretion

Higher concentrations (10 – 500 mg/d) of iodide ions influence all the important steps of iodine metabolism and indirectly inhibit the secretion of thyrotropin. The active uptake of iodide by the thyroid gland is inhibited by high concentrations of iodide in the blood. At the same time, the organic binding of iodine is inhibited (Wolff – Chaikoff effect), resulting in the inhibition of hormone synthesis.

The inhibition of hormone release from Tg is clinically most significant and is the cause of the immediate (after ca. 2 h) action of iodide. This inhibition is due to the blocking of the proteases involved. However, the thyroid-depressing effect decreases with continuous use. For this reason, therapy with iodides (with the

Table 2. Pharmacokinetic data of antithyroid substances

	Methylthiouracil	Propylthiouracil	Carbimazole	Methimazole, Thiamazole
Notes	not commercially available in Germany since July 92		prodrug (inactive) enzymatic conversion to methimazole during or directly after resorption	active metabolite
Initial dose	400 – 600 mg/d	300 – 600 mg/d	30 – 60 mg/d	20 – 40 mg/d

	agranulocytosis in 1 – 3 % of all cases			agranulocytosis in 0.3 – 0.6 % of all cases

exception of iodine prophylaxis) in preparation for thyroidectomy in a thyrotoxic crisis or hyperthyroidal struma (Plummering) is possible only for a duration of 2 – 6 weeks. The agents used are KI, Lugol's solution, and organic iodine preparations.

Polonium iodide, which was administered as an i. v. preparation until now, is no longer produced for economic reasons.

Lithium salts, which have attained considerable importance in the treatment of mental diseases, inhibit the proteolytic release of the thyroid hormones [1]. As a result of their side effects and small therapeutic range, lithium salts are reserved for special indications such as thyrotoxic crisis, especially when caused by the i. v. application of contrast media [13].

In preoperative thyroid depressant therapy for hyperthyreosis, the thyroid depressants mentioned in Section 3.2 and symptomatic treatment with β-blockers are preferred [14].

3.4. Inhibitors of the Conversion of T_4 to T_3

Blockers are used in the clinical symptomatic treatment of hyperthyreosis. The agent of choice, propranolol, inhibits the conversion of T_4 to T_3. In the case of PTU (iodization inhibitor), the blockage of peripheral deiodination of T_4 to T_3 is being discussed as an additional mechanism of action. Glucocorticoids, which are intravenously administered in the treatment of thyrotoxic crisis, are also believed to inhibit the peripheral conversion of T_4 to T_3. The principle of action of the conversion inhibitors is preferentially employed in the treatment of thyrotoxic crisis [1].

3.5. Radioiodine

A radioactive form of iodine, ^{131}I [*7790-26-3*], $T_{1/2}$ 8 d, γ energy 364 keV, is used in the treatment of hyperthyreosis in Morbus Basedow or thyroid autonomy, in the treatment of differentiated thyroid carcinomas after thyroidectomy, in struma therapy, in recurrences after strumectomy, and in metastasizing thyroid carcinomas that store iodine [15, 16]. Like the stable isotope ^{127}I, it enters thyroid metabolism and is incorporated into the thyroid hormones. The radiation comprises 90 % of β-particles and 10 % of γ-rays. As a result of the low range of β radiation (1 mm), thyroid tissue is largely destroyed selectively. The γ radiation can be used for diagnostic purposes. According to recommendations made by the German Federal Board of Health (BGA), itshould be used only in the case of thyroid malignancies (whole body scintigraphy) or to calculate the dosage for radioiodine therapy.

3.6. Chemical and Physical Properties of Thyroid Depressants

Aminothiazole (INN), 2-aminothiazole (IUPAC) [*96-50-4*], $C_3H_4N_2S$, M_r 100.14, *mp* 93 °C from benzene and petroleum ether, *bp* 140 °C (1.47 kPa). Crystalline substance, soluble in hot water, slightly soluble in cold water, ethanol, and ether, readily soluble in dilute hydrochloric acid and in 20 % sulfuric acid.

This agent is synthesized according to the King method by the conversion of paraldehyde with thiourea in the presence of sulfuryl chloride [17].

Benzylthiouracil (INN), BTU, 6-benzyl-2,3-dihydro-2-thioxo-4(1*H*)-pyrimidinone (IUPAC) [*33086-27-0*], $C_{11}H_{10}N_2OS$, M_r 218.30, *mp* 223 –224 °C. The synthesis is described in [18].

Methylthiouracil (INN), MTU, 2,3-dihydro-6-methyl-2-thioxo-4(1*H*)-pyrimidinone (IUPAC) [*56-04-2*], $C_5H_6N_2OS$, M_r 142.18, *mp* 326 –331 °C with decomposition; sublimes. White, finely crystalline, odorless powder with a slightly bitter taste, light-sensitive.

Solubility: 1:2000 – 2500 in water, 1:130 – 150 in boiling water, 1:800 in ethanol, and 1:1300 in 85 % glycerol. Readily soluble in alkali metal hydroxide and ammonia solutions, and methanol, slightly soluble in acetone, chloroform, and ether. Sparingly soluble in dilute mineral acids, and practically insoluble in benzene. The synthesis is conducted by reacting thiourea with ethyl 3-oxobutyrate [18].

Propylthiouracil (INN), PTU, 2,3-dihydro-6-propyl-2-thioxo-4(1*H*)-pyrimidone (IUPAC) [*51-52-5*], $C_7H_{10}N_2OS$, M_r 170.23, *mp* 219 – 221 °C. White, finely crystalline, bitter tasting powder.

Solubility: 1:900 in water at 20 °C, 1:100 in boiling water, 1:60 in 90 % ethanol, and 1:60 in acetone. Very slightly soluble in ether, chloroform, and benzene. In an aqueous medium, PTU is a monobasic acid with a pK_a of 8.3 (20 °C). It dissolves in aqueous ammonia and aqueous alkali metal hydroxide with formation of salts.

PTU is made by the condensation of thiourea with ethyl 3-oxohexanoate [18]. A summary of the analytical data of PTU is given in [19].

Carbimazole (INN), CBZ, ethyl-3-methyl-2-thioxo-4-imidazoline-1-carboxylate (IUPAC) [*22232-54-8*], $C_7H_{10}N_2O_2S$, M_r 186.23, *mp* 122–125 °C. White or creamy crystalline powder with a characteristic odor.

Solubility: 1:5000 in water at 20 °C, 1:50 in ethanol, 1:330 in ether, 1:3 in chloroform, and 1:17 in acetone.

It is produced by the reaction of methimazole with ethyl chloroformate [20].

Methimazole, thiamazole (INN), MMI, 1-methyl-2-imidazole thiol (IUPAC) [*60-56-0*], $C_4H_6N_2S$, M_r 114.17, *mp* 146–148 °C from ethanol, *bp* 280 °C with slight decomposition. White, crystalline powder with a weak characteristic odor and a bitter taste, light-sensitive.

Solubility: readily soluble in water (1:5), soluble in ethanol (1:5), and chloroform (1:5), slightly soluble in ether (1:125) and petroleum ether.

It is produced by the reaction of aminoacetaldehyde diethylacetal with methylisothiocyanate or of thiocyanic acid with N-methylaminoacetals [21]. A collection of analytical data is given in [22].

Thibenzazolin (INN), 1-3-bis(hydroxymethyl)-2-benzimidazolinethione (IUPAC) [*6028-35-9*], $C_9H_{10}N_2O_2S$, M_r 210.26, *mp* 160–162 °C. Colorless crystals having a very bitter taste, soluble in dilute alkali metal hydroxide solutions.

It is synthesized as described in [23], and is a thyroid depressant with a sedative effect. A selection of the common trade names of the substances mentioned above is given in [24].

1. History [1–4], [6], [11], [15]

Because of its luster and softness, tin was usually assigned to the planet Jupiter, more rarely to Venus. The name of the element is derived from the Old High German *zin* and the Norse *tin*. The symbol Sn from the Latin *stannum* was proposed by BERZELIUS. Historically tin is of major cultural importance, being an essential component of the copper alloy bronze which gave its name to the Bronze Age. The first bronze objects appeared in Egyptian tombs dating from the end of the 4th millennium B.C.

Pure tin was first produced in China and Japan around 1800 B.C. Around 600 B.C., the ancient Egyptians occasionally placed pure tin artifacts in mummies' tombs. Tin is not only an essential constituent of tin bronze, but is also a constituent of lead alloys for solders and tin plating. Tin and especially its alloys have shaped the development of many geographical regions, e.g., China, Indochina, Indonesia, India, the Near East, North Africa, and Europe.

The cultural and historical importance of tin from the Middle Ages to early modern times lay

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_049

in its use for sacred objects, articles of daily use, and jewelry.

There is no historical evidence concerning the oldest methods of tin extraction. It is fairly certain that in 100 B.C. in Cornwall, England, tin was smelted from very pure ore over wood fires in pits and later in small furnaces. Up to the 1200s, Cornwall provided most of Europe's tin. Today, these deposits are virtually exhausted. Tin was probably produced in Bohemia around 1150. Also, the first tin mines were opened in Saxony at this time, and these supplied European requirements until they were destroyed in the Thirty Years War. Then, as these various deposits gradually became exhausted and as ocean transport developed, tin from overseas became dominant.

The largest tin mines are in Asia, the most important ore-supplying countries in the world being Malaysia and Indonesia, followed by China. The second largest tin-producing region includes Brazil and Bolivia. The countries exporting the largest quantities of tin ores also produce the most tin metal.

World annual production has developed as follows:

ca. 1800	9 100 t
ca. 1850	19 000 t
ca. 1900	91 900 t
ca. 1950	172 100 t
1980	243 600 t
1990	225 600 t

The principal consumer countries are the United States, Japan, China, and Russia.

2. Properties

Physical Properties [1], [2], [4], [16–19], [20]. Tin, Sn, exists in two crystalline modifications, the α- and β-forms. A third modification may also exist. Some physical properties of α- and β-tin are listed in the following. (see right column)

In the periodic table, tin lies on the boundary between metals and nonmetals. The transformation of the α- to the β-modification is accompanied by a complete change of lattice structure, affecting the physical, chemical, and mechanical properties. Also, at 170 °C there is a secondorder transformation accompanied by a discontinuous change in the lattice parameters and thermomechanical properties. A tetragonal highpressure modification of tin, stable between 3500 and 11 000 MPa, is described in the literature, the lattice constants being $a = 381$ pm and $b = 348$ pm.

Natural isotopes	10
Relative atomic mass	118.69
Crystal structure	
α-Sn (gray tin)	fcc (A_4) diamond type
β-Sn (white tin)	tetragonal (A_5)
Transformation temperature α-Sn $\leftrightarrow$ β-Sn	286.2 K
Enthalpy of transformation	1966 J/mol
Lattice constants at 25 °C	
α-Sn	$a = 648.92$ pm
β-Sn	$a = 583.16$ pm
	$c = 318.13$ pm
Density of β-tin	
20 °C	7.286 g/cm^3
100 °C	7.32 g/cm^3
230 °C	7.40 g/cm^3
Density of α-tin	5.765 g/cm^3
Density of liquid tin	
240 °C	6.992 g/cm^3
400 °C	6.879 g/cm^3
800 °C	6.611 g/cm^3
1000 °C	6.484 g/cm^3
Molar heat capacity of β-tin	
25 °C	27.0 J mol^{-1} K^{-1}
230 °C	30.7 J mol^{-1} K^{-1}
Liquid	28.5 J mol^{-1} K^{-1}
Melting point	505.06 K
Enthalpy of fusion	7029 J/mol
Boiling point	2876 K
Enthalpy of vaporization	295 763 J/mol
Vapor pressure	
1000 K	9.8×10^{-4} Pa
1800 K	750 Pa
2100 K	8390 Pa
2400 K	51 200 Pa
Cubic coefficient of expansion	
α-tin at −130 °C to +10 °C	14.1×10^{-6} K^{-1} to 4.7×10^{-6} K^{-1}
β-tin at 0 °C	59.8×10^{-6} K^{-1}
β-tin at 50 °C	69.2×10^{-6} K^{-1}
β-tin at 100 °C	71.4×10^{-6} K^{-1}
β-tin at 150 °C	80.2×10^{-6} K^{-1}
Molten tin at 700 °C	105.0×10^{-6} K^{-1}
Coefficient of thermal conductivity of β-tin at 0 °C	0.63 W cm^{-1} K^{-1}
Surface tension	
232 °C	0.53 – 0.62 N/m
400 °C	0.52 – 0.59 N/m
800 °C	0.51 – 0.52 N/m
1000 °C	0.49 N/m
Dynamic viscosity	
232 °C	2.71×10^{-3} Pa · s
400 °C	1.32×10^{-3} Pa · s
1000 °C	0.80×10^{-3} Pa · s
Specific electrical resistivity	
α-tin at 0 °C	5×10^{-6} Ωm
β-tin at 25 °C	11.15×10^{-6} Ωm
Transition temperature for superconductivity	3.70 K
Magnetic susceptibility of β-Sn	2.6×10^{-11} m^3/kg

The transformation of β-tin (white tin) into α-tin (gray tin) is of practical importance, as it involves a volume increase of 21 %. The transformation process requires a high energy of activation, and can be very strongly hindered. White β-tin can therefore exist for many years at $-30\,^{\circ}C$. The presence of α-tin seed crystals is important for the transformation process, and these are formed by repeated phase transitions. Foreign "elements" also affect the transformation temperature and rate. These can consist of impurities and deformations. The effect of impurities on transformation behavior is described in [21]. Tin vapor consists of Sn_2 molecules.

Mechanical Properties [1], [2], [4], [20–23]. Mechanical properties are not of great relevance to most applications of pure tin. The most important are listed in the following:

Yield strength at 25 °C	2.55 N/mm^2
Ultimate tensile strength	
−120 °C	87.6 N/mm^2
15 °C	14.5 N/mm^2
200 °C	4.5 N/mm^2
Brinell hardness (10 mm, 3000 N, 10 s)	
0 °C	4.12
100 °C	2.26
200 °C	0.88
Modulus of elasticity E	
−170 °C	65 000 N/mm^2
−20 °C	50 000 N/mm^2
0 °C	52 000 N/mm^2
40 °C	49 300 N/mm^2
100 °C	44 700 N/mm^2
200 C	26 000 N/mm^2

Chemical Properties [1], [2], [4], [20]. Tin has the atomic number 50 and is a member of group 14 of the periodic table. The electronic configuration is $1s^2 2s^2 p^6 3s^2 p^6 d^{10} 4s^2 p^4 d^{10} 5s^2 p^2$. Tin can be di- or tetravalent. It is stable in dry air, but is considerably more rapidly oxidized at a relative humidity of 80 %. Bright metallic tin becomes dull within 100 d even in indoor atmospheres. Oxygen is rapidly and irreversibly chemisorbed, and the oxide layer formed grows at an exponentially increasing rate. Typical impurities present after metallurgical production (e.g., Sb, Tl, Bi, and Fe) promote oxidation. Treatment with carbonate or chromate solutions leads to passivation.

Molten tin at temperatures up to ca. 500 °C picks up oxygen from the air at a rate that obeys a parabolic law, a result of the compact layer of oxide formed.

Gaseous water and nitrogen do not dissolve in solid tin. Dissolution in molten tin only occurs at high temperatures (ca. $> 1000\,^{\circ}C$). Under the conditions of electrochemical reduction in hydrochloric acid solutions, atomic hydrogen forms SnH_4, and elemental nitrogen forms Sn_3N_4.

Tin is stable towards fluorine at room temperature, but SnF_2 or SnF_4 are formed at higher temperatures.

Rapid and vigorous reactions occur with chlorine, bromine, and iodine, these reactions being accelerated by moisture and elevated temperatures. The reaction products are $SnCl_4$, $SnBr_4$, SnI_2, and SnI_4.

Sulfur reacts rapidly with molten tin at $> 600\,^{\circ}C$ to form the sulfides SnS, Sn_2S_3, and SnS_2. The reaction rate is lower above 900 °C, and only SnS is formed.

Reaction with hydrogen sulfide is slow and only occurs in the presence of oxygen and moisture. Sulfur dioxide reacts with molten tin to form SnO_2 and S, and a molten solution of tin in copper reacts with SO_2 to form SnO_2 and Cu_2S (an important reaction in pyrometallurgy). Tin is stable towards pure hot water, steam, and dry ammonia. Nitrogen oxides only react with molten tin.

Tin is amphoteric, reacting with both strong bases and strong acids with evolution of hydrogen. Having a normal electrode potential of −0.136 V, tin lies between nickel and lead in the electrochemical series.

With sodium hydroxide solution, tin forms $Na_2[Sn(OH)_6]$, and with potassium hydroxide solution $K_2[Sn(OH)_6]$.

Tin reacts slowly with acids in the absence of oxygen. The high hydrogen overvoltage is caused by a layer of atomic hydrogen at the metal surface preventing further attack. Vigorous reactions occur with nitric acid, the rate depending on the acid concentration. The reactions are very vigorous with 35 % acid, but complete passivation can occur at concentrations > 80 %. Tin is stable towards fuming nitric acid. While hydrogen fluoride does not attack tin, hydrochloric acid reacts even at a concentration of 0.05 % and temperatures below 0 °C. Tin is not attacked by sulfurous acid or by < 80 % sulfuric acid.

The most important use of tin and tin-plated materials is in the preserved food industry. For this reason, the possibility of reactions of tin with certain organic acids is important. Lactic, malic, citric, tartaric, and acetic acids either do not react at all at normal temperatures or do so to a negligible extent, especially in the absence of atmospheric oxygen. This is also true of alcohols and hydrocarbons.

3. Occurrence; Ore Extraction and Beneficiation

The average concentration of tin in the earth's crust is estimated to be 2 – 3 ppm, comparable to cerium and yttrium. Owing to the high atomic mass of tin and the high density of its important minerals, its volume concentration is very low. However, it occurs in only a small number of locations, where consequently its relative abundance is high. In general, 1000-fold enrichment is necessary to give workable tin deposits, i.e., with a tin content of at least 0.2 %. The question of whether a deposit can be economically extracted, for a given world market price level, depends on the mining conditions. For example, there are deposits in Bolivia containing 1 % Sn which cannot be economically extracted, whereas in South East Asia placer deposits containing 0.02 % Sn are successfully mined.

3.1. Minerals

Native tin occurs only very rarely and has only been identified with certainty in Canada.

Cassiterite, SnO_2, is the most economically important tin mineral. It forms tetragonal crystals, has a Mohs hardness of 6 – 7, a density of 6.8 – 7.1 g/cm^3, and a tin content of up to 79 %. The color is usually brown to brownish black. The presence of Ti, Fe, Nb, Ta, or Mn can lead to colors varying from gray to white. Contact deposits of cassiterite can be combined with, e.g., magnetite, arsenical iron pyrites, or zinc blende. Placer deposits of cassiterite are of major importance. "Wood tin" consists of gel-like or very fine grained aggregates of cassiterite. Cassiterite is an oxidic mineral and is chemically very resistant, in particular towards weathering.

Stannite (bell metal ore), $Cu_2(Fe,Zn)SnS_4$, forms tetragonal crystals, has a Mohs hardness of 4, a density of 4.4 g/cm^3, and a tin content of up to 27.6 %. Its color is steel gray with an olive green tinge. It is chemically less resistant than cassiterite, seldom occurs in hydrothermal deposits, and is of little economic importance.

Hydrocassiterite (varlamoffite), H_2SnO_3, is a tetragonal gel-like stannic acid. It occurs in Bolivia, usually accompanying cassiterite.

Other tin minerals include teallite, (Sn,Sb)S; herzenbergite, SnS; franckeite, $Pb_5Sn_3Sb_2S_{14}$; cylindrite, $Pb_3Sn_4Sb_2S_{14}$; thoreaulite, $SnTa_2O_7$; hulsite, (iron tin borate); and stokesite, $CaSn(Si_3O_9) \cdot 2\,H_2O$. None are of economic importance.

3.2. Deposits

The economically important tin deposits are closely associated with acidic to intermediate magmatic rocks which were formed in the orogenic phases of the earth's history. Tin, a volatile metal, was deposited primarily during the pegmatitic, pneumatolytic, or hydrothermal phase in the region of the exo- or endocontact of the intrusive bodies. The economically much more important secondary tin deposits exist as eluvial, alluvial, or marine placer deposits which can be near to or remote from these acidic magmatic rock complexes. An overview of the ore reserves and of the amounts extracted in 1990 is given in Table 1.

Table 1. Tin ore reserves and mine outputs for various countries in 1990

Country	Ore reserves (t metal content)	Output (t metal content)
Malaysia	1 200 000	28 500
Thailand	1 200 000	14 600
Indonesia	1 550 000	31 700
Bolivia	980 000	17 300
Russia	1 000 000	13 000
China	1 500 000	35 800
Australia	330 000	7 400
Brazil	400 000	35 100
Zaire	200 000	1 600
United Kingdom	260 000	3 200
South Africa	50 000	1 100
Nigeria	280 000	200
Others	765 000	17 000
World total	9 715 000	210 700

Primary deposits originate from the pegmatitic formation of cassiterite in contact with granites or their secondary rocks. Cassiterite occurs there in idiomorphic pyramidal crystals of > 2 mm diameter. These tin-bearing granites and pegmatites typically include the minerals quartz, albite, potassium feldspar, muscovite, and cassiterite. Columbite is an important accompanying mineral. Deposits of this type are found in central and southern Africa, Brazil, and Russia (Siberia). They account for < 5 % of world production.

Cassiterite quartzes of the pneumatolytic catathermal phase were formed in vein fissures of granites and their secondary rocks. Individual veins or lodes can have a tin content of up to 3 %. They can be 0.2 – 1 m thick and up to 200 m deep.

There are various types of paragenesis of the granites, leading to the greisen type (mica – feldspar – quartz formed by pneumatolysis with fluorspar, lepidolite, and tourmaline), the topaz – quartz type, the feldspar – quartz type, and the quartz type. Such deposits contain ca. 20 % of the world's tin reserves, and are found in Malaysia, Russia (Siberia), and Germany (Erzgebirge in Saxony).

Cassiterite – sulfide deposits of the hydrothermal phase are formed as vein ores associated with intrusions of granodioritic rocks, or are formed by remigration of the metal content of older pegmatitic tin deposits caused by younger acidic subvolcanoes. Characteristic of these types of deposit is the paragenesis of cassiterite with stannite, iron pyrites, arsenical iron pyrites, galena, zinc blende, magnetic iron pyrites, and copper sulfides. These deposits, which can be very large, are mined in Bolivia, Russia, southern China, Thailand, Burma, Australia, South Africa, and also England. They constitute ca. 15 % of the world's tin reserves.

Because cassiterite is resistant to weathering and is hard and dense, the weathering of the primary tin-bearing rocks enables it to become concentrated as it is transported to form secondary deposits, i.e., eluvial, deluvial, or marine placers.

Eluvial placers are formed by intense weathering and breakdown of cassiterite-containing granites or granodiorites, especially under tropical climate conditions. The lighter minerals are washed out or carried away by wind, while the cassiterite and other heavy minerals remain behind and can become concentrated in deposits of considerable thickness, as in Malaysia and Zaire. Very coarse and deluvial placers are also formed by gravitational enrichment due to landslips and eluviation at the bottom of mountainsides.

Alluvial or fluviatile placers are formed by the transport of weathered tin-bearing rocks by flowing water derived from atmospheric precipitation. The softer and lighter components of the rock are more extensively size reduced and therefore transported further than the hard, resistant cassiterite minerals, which sink due to their high density and are deposited at points where flow rates are low. The most important alluvial placer deposits are in central Africa (Zaire, Ruanda), western Africa (Nigeria, Niger), and Brazil.

Marine placers are formed where primary tin-bearing rock complexes have been directly transported by surf, or where rivers have carried the cassiterite-containing sediment into the sea, where it is then deposited in coastal strips. These are the most important deposits, and represent ca. 60 % of the world's workable reserves. The largest of these deposits are in southeast Asia, the coast of Thailand, the Thai Island of Phuket,in Malaysia, and on the Indonesian Islands of Bangka and Billiton.

Secondary deposits usually have tin contents of 0.05 – 0.5 %, reaching 3 % in some cases. Marine placers have tin contents of 0.01 – 0.03 %. At present, deposits containing 0.1 % Sn are workable by the open-pit method. For underground mining, deposits should contain 0.3 % Sn.

3.3. Mining

Primary tin ores are extracted by underground mining. Depths can reach 1000 m in exceptional cases. Most of the technologies used in nonferrous metal mining are used, the method in a given situation being determined by the thickness, shape, and orientation of the ore body, and geological factors.

In secondary deposits, the loosely packed weathered hard mineral rock which contains the cassiterite together with associated deposits of sand and gravel is extracted by high-production loading techniques which also perform prelimi-

nary classification. General local conditions, including the state of economic development in the region, have a great influence on the mining conditions. For example, in Zaire, surface eluvial deposits (weathered pegmatites) with tin contents of up to 0.15 % are extracted by conventional open-pit methods. In Thailand, Malaysia, and Indonesia, loose alluvial and marine deposits in river valleys and in the undersea regions just off the coast are extracted by dredging shovels, dragline excavators, chain and bucket excavators, and similar equipment specially designed for local conditions. The initial separation of gangue and other foreign materials (e.g., wood) is performed by this equipment. Cassiterite in thick deposits of loose sediments and coarse detritus in Southern China and Thailand is treated with powerful water jets operating at pressures of up to 1.5 MPa. These generate a mixture of water and heavy sand which is then fed to the treatment plant.

Off the coasts of Indonesia, Thailand, and Malaysia, chain and bucket excavators are used to extract cassiterite from alluvial deposits under water at depths of up to 40 m. This also gives a preliminary beneficiation.

3.4. Ore Beneficiation [11], [24–28]

The beneficiation of primary tin ores is difficult. The principal mineral, cassiterite, is nonmagnetic and is not suitable for flotation, so that mainly gravimetric sorting processes must be used. Furthermore, cassiterite is often strongly intergrown, and the accompanying minerals behave similarly to cassiterite during processing.

Current technologies are characterized by controlled multistage size reduction of the ores and separation of the cassiterite released after each size reduction stage using sorting methods based on density. Screen jigs and shaking tables of various designs are used. However, very small particles ($< 30\,\mu m$) cannot be processed to give satisfactory yields and production rates. If the degree of intergrowth of the ores requires finer grinding, as is increasingly the case with ores from Russia, the United Kingdom, Bolivia, South Africa, and Portugal, the flotation method for sorting particles $< 100\,\mu m$ is sometimes used. This technique was also used for the tin ore from the Altenberg region of Saxony, whose mines were closed in 1990. The following stages of beneficiation of primary tin ores are used:

Ores with an average degree of intergrowth are concentrated mainly by processes based on density. Flotation is increasingly used to sort fine-grained material and ground middlings obtained by the density-based sorting process, and has now become the preferred method for treating the most finely intergrown, complex tin ores. Flotation of cassiterite with particle sizes between 40 and 10 µm is mainly carried out with arsonic acids.

The flow diagram (Fig. 1) shows the flotation of primary tin concentrates to remove sulfides of similar paragenesis, followed by flotation of cassiterite from the preconcentrate, and magnetic separation of paramagnetic minerals from the flotation product.

Composition ranges for complex tin concentrates are:

Sn	5.6 – 60 wt %
S	1.0 – 15 wt %
As	0.1 – 3 wt %
Sb	0.1 – 2 wt %
Bi	0.1 – 0.5 wt %
Cu	0.1 – 0.7 wt %
Pb	0.1 – 3 wt %
Zn	0.1 – 4 wt %
Ag	up to 500 ppm
W	0.1 – 5 wt % WO_3
Nb/Ta	1 – 3 wt % $Nb_2O_3 + Ta_2O_3$

The ores from placer deposits are thoroughly broken down by natural weathering processes which separate the material roughly according to the rate at which it settles out of suspension. The fine-grained cassiterite is mixed with coarser sand or gravel. On board the floating dredges, which operate in artificial dredging ponds or natural surface waters, there is ore beneficiation equipment which produces a preconcentrate for further processing on shore (Fig. 2). The ore passes through a drum screen which removes coarse gravel (10 – 20 mm), wood, and other foreign bodies. The material passing through the screen is desludged in a hydrocyclone, and treatment on a three-stage screen jig then produces heavy metal concentrate for further processing on shore.

The ore obtained from placer deposits on land using water cannons or from the seabed using special ships with suction pumps is processed using conventional ore beneficiation methods such as screen jigs or screen troughs.

Figure 1. Flotation of primary tin ores

Concentrates from placer deposits are relatively pure; a typical analysis follows:

Sn	70 wt %	Ni	0.01 wt %
As	0.1 wt %	Ta_2O_5	0.2 wt %
Sb	0.05 wt %	Nb_2O_5	0.1 wt %
Pb	0.008 wt %	WO_3	0.05 wt %
Cu	0.005 wt %	SiO_2	5.0 wt %
Zn	0.01 wt %	CaO	0.1 wt %
Bi	0.015 wt %	TiO_2	0.1 wt %
Fe	0.3 wt %	Al_2O_3	1.0 wt %

Figure 2. Preparation of secondary tin ores (placer deposits) on floating dredgers

4. Smelting

4.1. Fundamental Theory of Smelting

[1–3], [5], [29–34]

Because the most important tin-bearing mineral in tin ore is cassiterite (SnO_2), the carbothermic reaction

$$SnO_2 + 2\,CO \rightleftharpoons Sn + 2\,CO_2$$

is of fundamental importance.

A theoretical consideration of tin smelting must include the temperature dependence of this equilibrium and the behavior of the important reactants (Sn, O, and C) and accompanying elements and impurities in the concentrate, e.g., Fe, Cu, Sb, Bi, Pb, Ag, Si, Ca, Al, Mg, Nb, Ta, etc., of which Fe is the most important. The equilibrium diagrams for Sn – O – C and Fe – O – C are of crucial importance in the reduction of tin. At temperatures above 1100 °C, not only the Sn but also the Fe present in the oxidic precursors is reduced, so that selective winning from industrial tin-containing raw materials, which always also contain iron, is impossible. Furthermore, in this temperature range, up to 20 % tin dissolves in iron, and iron – tin compounds (known as hard head) are formed at lower temperatures, so that iron-free tin cannot be obtained under these conditions. This restricts the advantage of using a high process temperature to give a faster reaction rate in carbothermic cassiterite reduction. Also, the technique of stably binding iron in fayalite, to enable tin reduction to be carried out selectively, though realized on a laboratory scale by WRIGHT [29], could not be scaled up to production conditions.

The elements involved in tin reduction can be divided into the following groups:

1) Elements more noble than tin are reduced at lower temperatures than tin, and dissolve in molten tin (e.g., Cu, Pb, and Sb)
2) Elements that are much less noble than tin and which are not reduced under the reduction conditions, but which act as important slag formers, such as Ca, Al, and Si in the form of their oxides
3) Iron, the most important accompanying element, which behaves similarly to tin
4) Gaseous compounds produced in the reduction process
5) Sulfur, which has an important role in the reduction and volatilization process of pyrometallurgical tin production

Both the iron and the slag formers must be removed in a liquid slag; this determines the minimum process temperature. The iron content of the metal product depends on the Fe/Sn ratio in the slag. This relationship, represented in Figure 3, illustrates the principal problem of tin production from oxidic raw materials. If a high tin yield is to be obtained, i.e., small losses of tin in the slag (e.g., < 10 %), high reduction temperatures must be used, giving an iron content in the tin of > 8 %, so that subsequent refining is more difficult. If a purer metal is desired (e.g., 0.5 % iron in the tin), there will be high losses of tin in the slag, whose tin content can be 10 – 25 %. These slags are starting materials for a second process stage.

Figure 3. Calculated Fe/Sn ratios in the metal and slag at equilibrium as a function of temperature

The reactions in the slag phase are of major importance for selective reduction, whereby SnO is an important component. Experiments on pure substances have shown that although SnO melts at 980 °C it is unstable below 1100 °C, decomposing into SnO_2 and Sn. The activity of SnO in $SnO - SiO_2$ melts obeys Raoult's Law between 1000 and 1250 °C. The negative free energies of mixing SiO_2 with FeO, ZnO, PbO, MnO, and MgO increase in this order, and increase the SnO activities in the silicate melts. The position of the metal – slag equilibrium in the reaction

$$Fe + SnO \rightleftharpoons Sn + FeO$$

is expressed by the distribution coefficient

$$K = \left(\frac{Sn}{Fe}\right)_{metal} \cdot \left(\frac{Fe}{Sn}\right)_{slag}$$

K should be as large as possible, and at the usual reaction temperature of 1000 – 1100 °C used in

tin metallurgy, should be ca. 300 to give an iron content of ca. 1 % in the tin.

Binary and ternary slag systems containing tin oxides have been thoroughly investigated [33] and give useful guidance for carrying out the tin reduction. However, practical results depend very much on the viscosity of the molten products, the density differences, the surface tension, and colloidal dispersion and chemisorption of the slags. Thus, under production conditions stronger bases displace SnO bound in silicate, and FeO increases the fluidity of the slags.

The difference between the kinetics of tin oxide reduction and iron oxide reduction affects the selectivity of the reduction process and hence the iron content of the tin and the performance parameters of the furnace systems. Other important parameters are the pore structure and particle size of the raw materials, the partial pressures of the reduction gases, removal of the reaction gases, formation of seed crystals and coatings, and heat transfer. Thus, from the point of view of reaction rate, the reverberatory furnace is not the best equipment for carrying out reduction as it contains a large slow moving mass of material with a large bed thickness where heat is supplied only from above. The poor heat transfer leads to an extremely low smelting capacity, i.e., < 0.7 t metal per m^3 furnace volume per day. Because slag formation is very slow, some of the tin reduced at the start of the process can be tapped off as a relatively pure, low-iron product before the entire charge is smelted.

In contrast, highly turbulent reaction systems lead to process rates orders of magnitude higher. Under practical reaction conditions above 900 °C, the reaction

$$SnO_2 + 2\,CO \rightleftharpoons Sn + 2\,CO_2$$

is rapid, and the reaction

$$C + CO_2 \rightleftharpoons 2\,CO$$

becomes rate determining. This is why oxygen has to be added to the mixture of solid charge and reducing carbon in the furnace.

World production of tin is two-thirds from oxidic and one-third from sulfidic raw materials. The main problem in treating sulfidic tin concentrates is their complex composition. As many impurities as possible are vaporized in an initial roasting stage.

Arsenic requires special treatment, as it is oxidized to As_2O_3 and As_2O_5, which combines with Fe_2O_3, formed by roasting, to give nonvolatile iron(III) arsenate. In practical operation, a somewhat reducing atmosphere is therefore produced by adding charcoal to the charge. Another possibility is to vaporize heavy metal chlorides by adding NaCl.

4.2. Special Aspects of the Winning of Tin from its Ores

Problems in ore beneficiation often lead to concentrates with low tin contents, as unacceptably high losses of material would occur if ore concentrates with higher tin contents were produced. Therefore, a pyrometallurgical "thermal ore beneficiation" stage is necessary prior to the actual reduction process. This is a volatilization process that exploits the fact that the iron compounds and other slag formers have low vapor pressures at 1000 – 1500 °C, while SnO and SnS volatilize very readily. This technique can also be used to treat tin-containing slags.

The vapor pressure of SnS is considerably higher than that of SnO. Therefore, in practice, SnS is vaporized and then oxidized to SnO and SO_2. Pyrites (FeS_2) added as sulfur source causes problems in later stages of the process, as the FeO formed must be slagged, and the SO_2 evolved makes waste-gas cleaning necessary. However, this is outweighed by the advantages of a high yield of tin at relatively low process temperatures.

Economic advantages can be achieved by using cheap sulfur-containing grades of heating oil as fuel in the roasting process.

The naturally occurring ore beneficiation process that takes place in cassiterite deposits in surface waters and the increasing use of ore concentration processes with finely intergrown ores lead to extremely fine grained materials. Processes of agglomeration or compaction would be very costly. For this reason, these types of raw material are usually treated in an ore reverberatory furnace.

The main problem in pyrometallurgical tin production processes is separating tin from iron. Under production conditions, simultaneous reduction of SnO and FeO cannot be prevented. Molten tin can dissolve large amounts of iron,

and intermetallic compounds, which are very difficult to separate, can be formed on solidification. To minimize this problem, tin production is carried out in two stages. In the first stage, under mild reduction conditions, a relatively pure tin and a rich slag are produced. The latter is treated under strongly reducing conditions in the second stage, giving a discardable slag and a very impure tin – iron compound. The metallic phase is returned to the first stage, where the iron is reoxidized. The two-stage process must be carried out such that the iron initially in the concentrate is eventually removed from the process in the waste slags.

4.3. Production of Crude Tin

4.3.1. General Aspects

The choice of a crude-tin production process involves consideration of factors associated with both raw materials and location, and the following questions must be posed:

1) Whether the raw materials are highly enriched concentrates with low levels of impurities
2) Whether the raw materials used are low-grade concentrates whose principal impurities are slag components
3) Whether complex raw materials containing at least one other valuable element (e.g., W, Nb, or Ta) are used

Other important factors include the availability of raw materials, energy costs, environmental considerations, and personnel costs.

4.3.2. Ore Preparation prior to Reduction

As a result of the problems described in Section 3.4 and also of the efforts to recover as much of the tin from the ore as possible, the tin content of the ore concentrate can range from 8 to 60 %. Hence in most cases, pretreatment is necessary, e.g., pyrometallurgical enrichment of low-grade raw materials, a roasting stage (sometimes with addition of fluxes), or a leaching operation.

4.3.2.1. Pyrometallurgical Enrichment of Low-Grade Concentrates [1–5], [28–30], [34–41]

Low-grade tin concentrates are subjected to pyrometallurgical enrichment. The tin is vaporized as sulfide, and then oxidized in the gas phase by atmospheric oxygen to form SnO_2. The nonvolatile components of the raw material are selectively removed, and with careful process control, 90 – 95 % of the tin can be recovered as an oxidized product containing 40 – 60 % Sn.

Optimum results are only obtained if the reaction of the sulfide with oxygen takes place exclusively in the gas phase; therefore, reducing conditions must be maintained in the furnace. Although gaseous sulfur is the best sulfiding agent from a thermodynamic viewpoint, pyrites is used almost exclusively under production conditions. If calcium sulfate is used, the disadvantage that energy is required for its dissociation must be balanced against the advantage that the CaO produced is a useful slag former.

Although the vaporization of tin as SnS is used in all production plants, there is no generally accepted model of the reactions that take place. However, it is probable that in view of the S/Sn ratios required, the available polysulfidic sulfur in the pyrites does not take part in the formation of tin sulfide. Furthermore, it can be deduced from the importance of the added carbon to the reaction product obtained and from the CO content or oxygen demand of the reaction gases that SnO_2 is reduced first to SnO in an intermediate stage and SnS is then formed by the reaction of SnO with FeS. This is supported by the fact that the pyrites or the FeS formed therefrom forms SnS more readily than does sulfur vapor, contrary to what would be expected from thermodynamic considerations.

These results, especially when supported by practical experience, show that the overall equation and the individual reactions are probably as follows [28]:

$$SnO_2 + FeS_2 + 1/2\,SiO_2 + C + 3/2\,O_2 \rightleftharpoons SnS + 1/2\,(2\,FeO \cdot SiO_2) + SO_2 + CO_2$$

$$FeS_2 \rightleftharpoons FeS + S$$

$$S + O_2 \rightleftharpoons SO_2$$

$$C + 1/2\,O_2 \rightleftharpoons CO$$

$$SnO_2 + CO \rightleftharpoons SnO + CO_2$$

$$SnO + FeS \rightleftharpoons SnS + FeO$$

$$2\,FeO + SiO_2 \rightleftharpoons 2\,FeO \cdot SiO_2$$

Pyrometallurgical enrichment of low-grade tin concentrates can be carried out in various types of furnace.

Initially, rotary and shaft kilns were used for the vaporization process. Although the operation of both types of equipment was technically sophisticated, there were considerable disadvantages, which eventually led to their abandonment. Apart from the high energy and fuel requirements typical of both systems, the shaft kiln process led to a relatively low direct yield of tin in the flue dust, mainly due to the production of matte, which required separate processing. The rotary kiln method led to a low tin concentration in the flue dust, and, for raw material of high iron content, to the formation of matte, and hence to a drum clinker, which had then to be processed in a shaft kiln.

High-capacity thermal concentration processes, already established on a large scale in the nonferrous metal industry, were therefore adapted to tin enrichment. The fluidized bed and the cyclone smelting processes were not used. Also, the flash smelting (levitation smelting) process has severe limitations because of the raw materials used. Good results could be obtained with concentrates in which most of the material had a particle size of 200 – 300 µm. Using such concentrates containing 10 – 12 % Sn, discardable slags containing 0.2 – 0.4 % Sn and flue dusts containing 50 – 60 % Sn could be obtained. On using low-grade concentrates that had not been desludged and which contained significant amounts of material with a particle size of 50 –60 µm, the amount of primary flue dust increases significantly, and the tin concentration in the flue dust sometimes decreases to < 40 %. Also, the tin content of the slags is unacceptably high (1 – 2 %).

The main disadvantage of the flash smelting process is that it imposes strict requirements on the physical form of the concentrate.

The slag blowing process, originally used for detinning the slags from the reduction process, has been increasingly used for enrichment of tin in low-grade concentrates and exploitable gangue from ore processing. These products were at first added to the initial smelting process, but they were later added in solid form directly to the blowing furnace. Smelting and blowing can be carried out in a single furnace, so that it is not necessary to build a special smelting plant. This enables capital and operating costs to be reduced.

An important part of the practical operation is the maintenance of the correct fuel – air mixture with uniform distribution of the fuel and air to the individual jets. Heating oil and natural gas are preferred because they are more easily metered than solid fuels. If pyrites is used as the sulfiding agent, an S/Sn ratio of 0.8 is necessary, which places high demands on the equipment for removing sulfur dioxide. When pyrites is used, only FeS is effective in the slag phase, so that only 50 % of the sulfur is used for sulfiding. If pyrrhotite (magnetic pyrites) or calcium sulfide is used, the S/Sn ratio need only be 0.4, and the emission of sulfur dioxide decreases by 50 %.

The good metallurgical results of the slag blowing process, in which flue dusts containing 65 – 70 % Sn and final slags containing 0.1 % Sn are obtained, must be balanced against the disadvantage of a batch process. This leads to nonuniform loading of the downstream plant, e.g., the waste heat recovery and gas cleaning equipment.

4.3.2.2. Roasting [1], [2], [4], [5], [11], [17], [32], [42–50]

The roasting process, not only converts sulfides to oxides, but also volatilizes major oxidic impurities (e.g., arsenic). Roasting can be an independent process, or a pretreatment prior to hydrometallurgical leaching. It is significant that the level of impurities As, Sb, Pb, and Bi in tin concentrates has increased in spite of great efforts to improve ore beneficiation technology. If the levels of As and Pb are > 0.1 %, and of Bi and Sb > 0.03 %, a roasting process, sometimes with the addition of a leaching stage, is both useful and necessary for the benefit of the final tin reduction and refining processes.

The important reactions in the roasting process are as follows (M = metallic impurity):

1) Dissociation
   $FeS_2 \rightleftharpoons FeS + 1/2\,S_2$
   $4\,FeAsS \rightleftharpoons 4\,FeS + As_4$
2) Roasting reactions
   $MS + 3/2\,O_2 \rightleftharpoons MO + SO_2$
3) Oxidation
   $MO + 1/2\,O_2 \rightleftharpoons MO_2$

Although the roasting reactions and especially the oxidation reactions are exothermic, addition of fuel is necessary in industrial-scale roasting processes. The pore structure of the material must be maintained to enable the gaseous metallic and nonmetallic impurities to be vaporized. The upper temperature limit for the roasting process is imposed by the melting point of the low-melting sulfide eutectic. However, the temperature should be kept as high as possible to prevent the formation of sulfates, e.g., lead and calcium sulfate.

A mildly reducing atmosphere is necessary to suppress sulfate formation and also prevent formation of higher nonvolatile oxides of the impurities (e.g., As_2O_5).

The roasting processes are carried out in multideck or rotary kilns. The use of fluidized-bed furnaces with carefully controlled operating parameters has been reported [48].

Chloridizing roasting is also suitable for the pretreatment of tin concentrates, owing to the high affinity of the main impurities for chlorine. However, problems can be caused by chloridation of tin, which itself then volatilizes as $SnCl_4$ and $SnCl_2$.

Chloridizing roasting of tin concentrates in rotary kilns is carried out in Thailand. The contents of lead and bismuth are lowered from 2.0 % to 0.04 %, and from 0.1 % to 0.02 %, respectively. The flue dust contains 10 % As, 3 % Sn, 20 % Pb, and 4 % Bi. Treatment of this product presents serious problems [2].

The processes for removing impurities by chloridation differ fundamentally from those for the volatilization of tin from concentrates, being based on the fact that a large phase field exists in the phase diagrams $Sn-HCl-H_2$ and $Fe-HCl-H_2$ between 900 and 1000 °C in which selective chloridation and volatilization of tin is possible without chloridizing iron.

The overall reactions are as follows (M = Mg, Ca, or Na):

$$SnO_2 + MCl_2 + CO \rightleftharpoons SnCl_2 + MO + CO_2$$

$$SnO_2 + Cl_2 + C \rightleftharpoons SnCl_2 + CO_2$$

$$SnO_2 + 2\,HCl + CO \rightleftharpoons SnCl_2 + H_2O + CO_2$$

The presence of iron oxide increases yield and reaction rate, which can only be explained by intermediate formation of $FeCl_2$:

$$4\,SnO_2 + 6\,FeCl_2 \rightleftharpoons 2\,Fe_3O_4 + 2\,SnCl_2 + 2\,SnCl_4$$

Here, the instability of iron chloride in the presence of tin oxide is the reason for the good separation of tin from iron. In a reducing atmosphere, i.e., in the presence of C or CO, only $SnCl_2$ is formed.

In the Warren Spring process [50], $CaCl_2$ is used as chloridizing agent, and the CaO formed is used in the reductive smelting by adding limestone in accordance with the following equations:

$$SnO_2 + CaCl_2 + C \rightleftharpoons SnCl_2 + CaO + CO$$

$$SnCl_2 + CaCO_3 + C \rightleftharpoons Sn + CaCl_2 + CO + CO_2$$

The industrial-scale reaction is difficult to carry out, as moisture resulting from the hygroscopic properties of the tin chloride and the quicklime must be avoided. The corrosive properties of the reaction gases make very high demands on the construction materials used.

A special form of roasting is the heating of high-tungsten tin concentrates with NaOH or Na_2CO_3 to give soluble Na_2WO_4, which can be leached out.

4.3.2.3. Leaching [1–4], [32], [47], [51–55]

In tin metallurgy, the main use of leaching processes is to remove typical impurities from the concentrate. Tin, which is nearly always present in the raw materials as SnO_2, can only be brought into aqueous solution if the SnO_2 is reduced to SnO in a precisely controlled CO/CO_2 atmosphere. It can then be extracted in acid or alkaline media. This procedure has not yet been operated on an industrial scale.

Only hydrochloric acid is used on an industrial scale to remove impurities by leaching, the typical impurities in the concentrate, Fe, Pb, Cu, Sb, or As, going into solution in the form of their

chlorides. Best results are obtained using > 20 % hydrochloric acid at 100 – 110 °C. Suitable reaction vessels are high-pressure, acid-resistant spherical boilers with a capacity of 20 t. This batch process must sometimes be repeated several times. The solids are removed by thickeners and vacuum filters, and the dissolved impurities are precipitated from the liquor by cementation on scrap iron.

The high costs of these special reactors, the batch mode of operation, and the expense of the process for recovering the hydrochloric acid have restricted the use of hydrochloric acid leaching to some special cases.

It is preferable to carry out chloridizing roasting before leaching out the impurities. This then only requires a dilute acid solution.

Leaching of tungsten-containing tin concentrates to recover tungsten is important. After digesting the ore with sodium carbonate in spherical boilers, the tungsten is converted to its hexavalent form, which is soluble in hot water. It is then precipitated from the neutral solution with $CaCl_2$:

$$Na_2WO_4 + CaCl_2 \rightleftharpoons CaWO_4 + 2\,NaCl_2$$

An easily filtered precipitate containing up to 60 wt % WO_3 (on dry basis) is obtained.

Tungsten can also be extracted from tin concentrates by leaching with an aqueous solution of ammonia:

$$H_2WO_4 + 2\,NH_4OH \rightleftharpoons (NH_4)_2WO_4 + 2\,H_2O$$

The concentration of WO_3 in the filtrate can reach 50 g/L, and this can be precipitated as artificial scheelite ($Ca[WO_4]$). The tungsten content of the tin concentrate can be reduced to 0.5 %.

Most of the tin can be leached from a tin concentrate containing 2 wt % bismuth with 5 % hydrochloric acid at 80 °C [46].

Treatment with sulfuric acid is used to remove iron present as carbonate in Australian tin concentrates. By removing gangue material in this way, the tin content of the concentrate is increased from 37.2 % to 47.1 %.

A process for the removal of arsenic from tin concentrates by bacterial leaching with *Thiobacillus ferrooxidans* has been tested in Russian research institutes [54].

The tin can be leached out of ores that are difficult to treat if these are first reductively smelted with $CuCl_2$ and HCl, in accordance with the following series of reactions [42]:

$$Sn + CuCl_2 \rightleftharpoons Cu + SnCl_2$$

$$Cu + CuCl_2 \rightleftharpoons Cu_2Cl_2$$

$$Cu_2Cl_2 + HCl \rightleftharpoons 2\,CuCl_2 + H_2$$

Tin is precipitated from solution by adding zinc, and copper by adding iron.

4.3.3. Reduction

As explained in Section 4.1, it is not possible to obtain high yield and high metal purity at the same time. Reduction is therefore carried out in two stages, the first stage giving a relatively pure metal (up to 97 % Sn) and a rich slag (8 – 35 % Sn). This slag is treated in a second stage, and sometimes in a third. Slag treatment processes are described in Section 4.3.4.

Various types of furnace are used for reduction. Very low grade ore in lump form can be treated in a shaft kiln. However, as most concentrates obtained in ore beneficiation are very finely divided, and agglomeration, e.g., by sintering, is impossible, other types of furnace must be used in this case. Reverberatory or rotary air furnaces are often used for reduction, and electric furnaces are also employed. Each furnace type has its own advantages and disadvantages.

4.3.3.1. Reduction in a Shaft Kiln [1–3], [5], [30], [56], [57]

Shaft kilns are historically the oldest type used for tin reduction. They have their origin in the old Chinese natural draught furnaces made of rammed clay held together with wooden posts and operated on mountainsides. The hearth was usually sloped so that the molten product ran off continuously. Modern shaft kilns are water-jacketed, and have a melting capacity of 5.5 – 8 t m^{-2} d^{-1}. The good heat transfer and the continuous method of operation give a higher melting capacity than is obtained in comparable reverberatory furnaces. The air flow rate must be low to prevent volatilization. Shaft kilns require raw material in lump form. The iron content must be as low as possible in order to limit the formation of hard head in the reducing atmosphere.

4.3.3.2. Reduction in a Reverberatory Furnace [1–3], [5], [30], [32], [58–61]

The necessity for treating fine-grained concentrates from ore beneficiation has led to the replacement of the shaft furnace by the reverberatory furnace, and this is today the most important type of reduction equipment used in tin metallurgy. Modern reverberatory furnaces have internal dimensions of 3 – 4 m width, 10 – 13 m length, and 1 – 1.5 m height. In a freshly lined hearth the height available for the molten charge is no more than 0.5 m. This increases with increasing wear of the furnace bottom. The bath volume of modern tin ore reverberatory furnaces is 20 – 50 m^3. As the tin is very fluid at the reaction temperatures (up to 1400 °C), high pressures can be produced at the bottom of the hearth. To prevent this, either holes must be provided in the steel sheet bottom to allow the tin to drip into a lower chamber where it can solidify in stalactite form, or the reverberatory furnace must have a water-cooled bottom so that the tin solidifies in the gaps between the bricks.

The refractory bricks and mortar used to line the furnace must be made of high-grade chrome-magnesite. This must be very pure because of possible reactions of SnO or Sn with iron oxides or silica. Chamotte can only be used above the slag zone. To avoid disturbance of the brickwork in the melting zone, charging is carried out through the roof.

The burners, which use heavy fuel oil, are situated on the narrow sides of the furnace. The furnaces operate discontinuously using the regenerative principle, the duration of a heat being 16 – 20 h. Specific melting capacities are in the range 1.2 – 2.0 $t\,m^{-2}\,d^{-1}$. Charge batches consisting of concentrate, carbon, and fluxes weigh between 40 and 70 t. Optimum results can only be achieved by extremely careful operation.

Thus, at the start of a new heat, the amount of material charged to the furnace should be limited, e.g., by adding the charge in two portions, to prevent a large drop in temperature. The amount of carbon added in the form of coke, coal, petroleum coke, or charcoal is determined by the tin and iron contents and also by the incidence of hard head. The carbon addition is adjusted so that coreduction of the iron is prevented as far as possible.

The furnace draught must be kept low to prevent entry of cold air and to maintain the oxygen content in the waste gas below 5 vol %, thereby minimizing oxidation of the tin.

The first tin can be tapped off after 4 – 5 h of a 24 h cycle. As this is comparatively pure, it is preferable to treat it separately. The material tapped off later separates into metal and slag in a settler outside the smelting furnace. Some furnaces have facilities for tapping off the metal and the slag separately.

Up to 6 % of the weight of charge material is converted to flue dust, which consists of entrained charge, SnO, and some SnS. Its tin content is therefore considerably higher than that in the charge material.

Compositions of products obtained when a relatively pure concentrate (> 70 % Sn) is treated in a reverberatory furnace are listed in Table 2. The amount of slag is relatively small (14 wt % of the charge), but the slag must undergo a further stage of processing because of its high tin content.

Table 2. Typical compositions of products from a reverberatory furnace (in wt %)

Component	Crude tin	Slag	Flue dust
Sn	97 – 99	8 – 25	40 – 70
Fe	0.02 – 2.0	15 – 40	0.8 – 4.0
As	0.01 – 2.0		0.1 – 0.7
Pb	0.01 – 0.1	0.1 – 0.5	0.2 – 1.6
Bi	0.003 – 0.02		0.01 – 0.1
Sb	0.005 – 0.2	0.01 – 0.02	0.1 – 0.4
Cu	0.001 – 0.1		0.02 – 0.05
Al_2O_3		7 – 12	≤1.0
SiO_2		10 – 30	≤2.0
CaO		4 – 14	≤0.6
MgO		1 – 4	≤0.6
S	0.01 – 0.05		≤1.0

A simplified flow diagram for the treatment of high-grade concentrates is shown in Figure 4.

The process flow diagram for low-grade, impure, and complex concentrates is considerably more complex. With high-grade concentrates, a tin yield, including that obtained from slag treatment, of 99.6 % can be achieved, as actual losses of tin can only occur in the waste slag and by loss of airborne dust. In the treatment of low-grade concentrates, the yields of tin may only be 95 %, and in exceptional cases 92 %, because of the numerous tin-containing waste products.

Control of the CO partial pressure, which determines the reduction potential, is more diffi-

Figure 4. Process for treating high grade concentrates (simplified)

cult in a stationary reverberatory furnace, which contains a slow-moving mass of charge, than in a shaft furnace, in which the coke and air move in countercurrent flow. This is also the reason for the poor heat transfer and hence the low rates of reduction and melting in a reverberatory furnace.

Under operating conditions, care must be taken that the slag formers do not melt too rapidly, as this impairs the contact between the furnace atmosphere and the unmelted charge. At the same time, the melting temperature of the slag must be as low as possible, so that the use of such slag formers as CaO and SiO_2 should be limited. Added lime is of special significance, because it displaces tin from silicate, can lead to calcium stannate formation if present in excess, and increases the melting point of the slag.

The effect of the slag constituents, especially on melting point and viscosity, is described in detail in [3]. In a process optimization/cost minimization exercise, it is always necessary to include the effect on costs of the amount of tin tied up in materials being recycled [59].

4.3.3.3. Reduction in Rotary Kilns [1–3], [5], [30], [32], [57–62]

Rotary kilns (rotary air kilns) are horizontal smelting units that operate batchwise. They have a higher melting capacity than stationary reverberatory furnaces, but lead to considerably more severe stress on the refractory lining. Operating procedures in two tin smelting works in Indonesia and Bolivia in which the reduction process is based on the rotary kiln principle are reported in the specialist literature [63]. The furnaces have a length of 8 m, a diameter of 3.6 m, a surface area of reacting material of ca. 22 m^2, and a specific melting capacity of $1.36 - 1.5\ t\,m^{-2}\,d^{-1}$.

The furnace availability (300 d/a) is superior to that of reverberatory furnaces (260 d/a). Also, there is less requirement for mixing operations or agitation of the melt by stirring (rabbling). The metallurgical results of both types of furnace are very similar. However, the considerably poorer stability of the refractory lining, the higher energy requirement, and the significantly larger quantities of flue dust are all disadvan-

tages. Separation of the tin from the slag has to be carried out outside the furnace in a settler.

Tin concentrate can also be reduced in short drum kilns in which the ratio of the length to the cross-section is 1. The metallurgical function is basically similar to that of the rotary kilns.

The compositions of the smelting products in an Indonesian tin smelting works in which high-grade concentrates are reduced in a rotary kiln are given in Table 3.

Table 3. Typical compositions of products from a rotary kiln at Mentok, Bangka (in wt %)

Component	Crude tin	Slag	Flue dust
Sn	99.78 – 99.83	14 – 25	60 – 72
Fe	0.089 – 0.144	15 – 26	1 – 4
Pb	0.010 – 0.031		
As	0.010 – 0.188		
Sb	0.005 – 0.010		
Bi	0.0025 – 0.003		
Cu	0.002 – 0.025		
SiO_2		8 – 24	0.2 – 2.0
CaO		2 – 10	1 – 1.2
MgO		2 – 4	
S			0.2

4.3.3.4. Reduction in an Electric Furnace
[1–3], [5], [30], [32], [58], [64–68]

Electric resistance and arc furnaces used in metallurgy are characterized by high reaction temperatures and low waste-gas volumes. Disadvantages are the necessity for thorough premixing of the raw materials and the batch operation. Tin smelting is often carried out in regions where electrical energy is less readily available than energy from other sources such as gas, coal, or oil. Wherever electric furnaces are used in tin metallurgy, the object is to utilize their advantages of high reaction temperature and the production of heat by the Joule effect directly in the smelting bath.

Because their reducing action is so effective, electric furnaces are particularly suitable for extracting tin from slag (see Section 4.3.4). In concentrates whose iron content is significantly less than 5 %, it is even possible to produce crude tin in a single stage, with tin levels in the slag of < 0.7 %.

Electric furnaces are used in many tin smelting works for primary tin production from concentrates. These concentrates are often imported, e.g., in Germany, France, Italy, Canada, and Japan, although tin concentrate producing countries, e.g., Brazil, Zaire, South Africa, Russia, Thailand, and China also use electric furnaces. The raw materials for the electric furnace process must be intensively mixed. Very fine-grained materials such as flue dust are pelletized. A moisture content of ca. 2 % must not be exceeded.

Typically, circular furnace vessels with an outside diameter of up to 4.5 m and a height of 1.5 – 3 m are used, or oval furnace vessels with dimensions $2.5 \times 1.8 \times 1.8$ m. Heating is carried out with three-phase electric arcs using graphite electrodes. In single-phase furnaces, the furnace bottom acts as the counterelectrode for the immersed graphite electrodes.

Both stationary and tilting furnaces are used. Linings of carbon bricks give a service life of up to three years. Electric currents of 6 – 20 kA at 50 – 150 V are used. Depending on the characteristics of the raw materials, energy consumption is 750 – 1400 kW · h/t concentrate (1300 – 1860 kW · h/t tin). Precise control of the electrode immersion depth is essential for good control of the process.

Electric furnace technology enables a wide range of process parameters to be used. For example, when low-iron concentrates are treated, a tin quality suitable for normal refining can be produced. The high-tin slags produced (up to 30 % tin) are treated in a second stage to recover the tin. If the iron contents are much greater than 3 %, the tin obtained has a high iron content (3 – 10 %).

It is also possible to operate at ca. 1400 °C by using strongly reducing conditions. A tin-containing slag is then obtained together with hard head containing ca. 40 % tin and 50 % iron. The iron can be removed by smelting with ferrosilicon in a second pass, and a crude tin containing ca. 1 % iron is obtained.

Great efforts have been made to overcome the disadvantage of batch operation of the electric furnace. For example, a continuously operated lengthened double chamber electric furnace has been reported in Russia. Each chamber has a hearth area of 1 m^2 and two electrodes. The reduced tin flows out of the first chamber over an air-cooled overflow, and the tin is extracted from the high-tin slag in a second chamber [68].

The process is still at the pilot stage. The furnace capacity is reported to be less than 10 t/d.

4.3.3.5. Other Reduction Processes [1–3], [5], [30], [58], [60], [69]

All the processes described above have disadvantages, and many other methods and types of equipment have therefore been suggested for the reductive treatment of tin concentrates, but few of these proposals have led to an industrial plant.

One of the few methods tested at full scale is the top blown rotary converter (TBRC) developed in the United States and based on the "Kaldo" converter used in ferrous metallurgy. Oxygen is blown onto the top of charge as the converter rotates about its axis, which is set at an angle. The volume of waste gas is very low as there is no ballast nitrogen. The favorable heat transfer to the charge leads to a high reaction rate. Disadvantages include batch operation, a high rate of wear of the refractory lining, and the complexity of the system for controlling the oxygen lance.

After completion of the reduction process, the tin is tapped off. The tin in the remaining slag is vaporized as chloride by adding calcium chloride, and a discardable slag is thereby produced. The tin chloride is scrubbed out of the waste gases and then precipitated as SnO_2 by adding CaO, regenerating $CaCl_2$.

The potential for transferring proven processes used in nonferrous metallurgy to tin metallurgy is discussed in detail in [69].

Apparently no completely new processes for reducing tin concentrates have become established in the industry because of the high capital investment required and the hidden risks involved.

4.3.4. Slag Processing [1], [2], [5], [32], [38], [47], [62], [63], [70–79]

The slags produced during the reduction of high-tin concentrates can contain 5 – 10 % of the tin. This can increase to 20 % in the case of low-grade and complex ores. One- or two-stage treatment of the slag is then necessary. It is in principle possible to use strongly reductive smelting (e.g., in a reverberatory or rotary furnace) or blowing processes to volatilize the zinc from the slag.

On reductive smelting, the tin and iron form an alloy, the so-called hard head, which is recycled to the primary tin production process. The secondary slag has such a low tin content that it can be removed from the process.

In the blowing process, the tin is converted into a flue dust, which is recycled to the primary smelting process. The slag, which usually has a high iron content, can be discarded.

Under production conditions, the intermediate products, e.g., the tin-containing secondary slag, the hard head, and the flue dusts, contain considerable quantities of tin. These are important for the economic operation of the process because of the amount of capital tied up if they are not immediately treated. The tin and iron balances in the treatment of a concentrate with a very high tin content and a low iron content are shown in simplified form in Table 4.

Table 4. Tin and iron balance for two-stage smelting of a concentrate containing 73 % Sn and 0.7 % Fe based on 1000 kg concentrate treated

	kg Sn	kg Fe
Smelting of concentrate		
Charge :		
1000 kg concentrate	730	7
95 kg hard head	38	42
220 kg coke/coal		2
40 kg flue dust	18	
11 kg recycled material	6	3
Total	792	54
Product :		
733 kg crude tin	730	2
200 kg primary slag	47	51
30 kg flue dust	15	1
Total	792	54
Smelting of slag		
Charge :		
200 kg primary slag	47	51
40 kg coke/coal		
Total	47	51
Product :		
100 kg secondary slag	1	8
95 kg hard head	38	42
10 kg flue dust	5	
2 kg Fe alloy		1
Total	44	51

The balance shows that the iron introduced into the concentrate smelting process with the concentrate and reducing agent (7 + 2 kg) must be removed from the slag smelting process in the secondary slag and iron – tin alloy (8 + 1 kg). Of

the tin in the concentrate, 6 % is in circulation in the primary slag (47 kg out of 730 kg).

However, the concentrates treated usually contain considerably more iron, so that a larger amount of primary slag and hard head are produced, and the amount of tin contained therein can rise to 20 % of the raw material used.

In practical slag smelting, the SnO in silica-rich slags is mainly present as $2\,SnO \cdot SiO_2$, and the high activity of the SnO in silica- and lime-containing slags decreases with increasing FeO contents, so that in practice simultaneous reduction of tin and iron occurs. Theoretically, it is only possible to produce crude tin and low-tin slag if the FeO activities are extremely low. However, the processes would proceed at high temperatures with large additions of reducing carbon.

The binary Fe – Sn phase diagram shows a miscibility gap at $> 1100\,°C$ between 20 and 50 wt % Fe. On cooling to room temperature, separation of α-iron first takes place, followed by formation of FeSn and $FeSn_2$. At room temperature, the region of the composition of the hard head is always in the α-iron/FeSn two-phase region.

Wright has found by calculation of the distribution constant K at equilibrium

$$K = \left(\frac{Fe}{Sn}\right)_{slag} \cdot \left(\frac{Sn}{Fe}\right)_{metal}$$

that the balance of the process is improved as the ratio in the first quotient increases, i.e., as the amount of iron removed in the slag increases. However, there must then be a higher iron concentration in the tin. If the tin in the primary slag is present as $2\,SnO \cdot SiO_2$, the reaction mechanism is as follows:

$$C + SnO \rightleftharpoons CO + Sn$$

$$CO + SnO \rightleftharpoons CO_2 + Sn$$

$$CO + FeO \rightleftharpoons CO_2 + Fe$$

$$CO + Fe_2O_3 \rightleftharpoons CO_2 + 2\,FeO$$

$$3\,FeO \rightleftharpoons Fe + Fe_2O_3$$

$$Fe + SnO \rightleftharpoons FeO + Sn$$

$$2\,FeO + SnO \rightleftharpoons Fe_2O_3 + Sn$$

Thus the reaction first occurs only at the surface of the carbon, and then via the iron oxides as intermediate phases. A high relative rate of reaction of carbon, slag, and reaction gas is therefore important for the reaction kinetics.

The reactions that occur in the detinning of slag are described in Section 4.3.2.1 (pyrometallurgical enrichment of low-grade concentrates), but here they start from SnO. As a matte phase must be present, the reaction will be:

$$SnO + FeS \rightleftharpoons SnS + FeO$$

As the slag is saturated with FeS, the amount of SnS formed is proportional to the activity of SnO in the slag, but indirectly proportional to the activity of FeO.

Reverberatory or electric furnaces are usually used in the reductive smelting process for the extraction of tin from primary reduction slags, though shaft kilns are occasionally used. The necessary intense reducing effect is achieved by adding 10 – 20 % reduction carbon and by operating at temperatures up to 1500 °C. In the electric furnace process, energy consumptions are 500 – 1000 kW · h/t, and 1 – 10 kg electrode is consumed per tonne of slag. The reaction products, i.e., the final slag and the hard head alloy, are separated in settlers and then granulated in water.

As highly turbulent conditions are favorable to the process, reductive detinning can be carried out with a lance ("submerged combustion"), which produces a high reaction rate by agitation of the bath. Methane or natural gas have been used as reducing gas, and experiments have also been carried out using hydrogen, carbon monoxide, and powdered solid fuels. Heat is produced by partial combustion of the injected gases and transferred to the molten slag. However, because SnO is volatile, 20 % of the tin goes into airborne dust, a further undesired tin-containing reaction product in addition to the hard head.

An effective method of detinning primary tin reduction slags is by the blowing process, which can be carried out in reverberatory furnaces or true blowing furnaces. Gypsum or pyrites can be used as the sulfur source. The gypsum is first reduced to CaS, and then reacts with SnO to form SnS and CaO. If pyrites is used, impurities such as Pb, Zn, or As are introduced into the metallurgical process, adding to the difficulties of

treating the tin-containing flue dusts. Blasting technology is also often used as the third stage of slag detinning. In the second stage, a thermal reduction, Sn contents of 2 – 5 % and FeO contents of ca. 30 % are obtained. The tin content of the molten slag in the furnace is reduced to ca. 0.5 % by addition of sulfur sources. The addition of pyrites can be up to 400 % of the theoretical amount calculated for the formation of SnS. Since smaller additions are possible in the case of acid slags, CaS is probably formed in basic slags. The treatment of primary slags in true blowing furnaces consists of blowing the pyrites into the molten slag. However, the process is discontinuous. The SnS vapor is oxidized in the furnace atmosphere, and recovered as SnO dust by filtration.

The slag blowing process can be carried out in furnaces of various designs, e.g., in a type of shaft kiln with a floor area of 0.5 – 6 m^2 and a water-cooled shaft 7 m in height. The charge of primary slag can be 5 – 20 t. Cyclone and short drum kilns are also used. Process parameters, e.g., ratios of sulfur source to oxygen, fuel to atmospheric oxygen, and tin to sulfur must be carefully controlled to obtain optimum results.

Other proposed methods of detinning primary tin slags, such as vacuum-assisted volatilization of SnO (which has a considerably lower vapor pressure than SnS), have not been used on an industrial scale [29].

5. Refining [1–3], [5], [32], [46], [47], [80–84]

The crude tin obtained by the reduction process is insufficiently pure for most applications.

Most national standards specify maximum contents of typical impurities. However, nonmetallic impurities such as oxygen and sulfur and less common impurities such as noble metals are neglected, and the tin content is simply determined by subtracting the total amount of analytically determined impurities from 100.

The following three standard grades are accepted internationally: Sn 99.0 %, Sn 99.75 %, and Sn 99.9 %.

There are some variations in these standards from country to country; the German standard is DIN 1704.

The level of impurities in the crude tin determines the extent of the refining operation. Treatment of very pure concentrates can give a tin content of up to 99.0 % in the crude metal. The main impurity is iron (0.8 %), the sum of all the other impurities being only 0.2 %. In the case of low-grade and complex concentrates, the situation is very different, the tin content of the crude tin obtained sometimes being only 92 %.

The impurities Fe, As, Sb, Cu, Ni, Pb, Bi, and the noble metals affect the amount of work involved in the refining process. The metals Zn, Cd, Mg, Si, Ca, Te, Se, and also sulfur and oxygen do not require special treatment, as they are present in the crude metal in only small concentrations, and are removed together with the other impurities during the various stages of purification.

The phase diagrams for tin and its typical impurities lead to the following conclusions:

In the temperature range between 1000 and 1300 °C used in pyrometallurgical reduction, the impurities are completely soluble with the exception of Fe and Cr.

Only Sb, Cd, Bi, Zn, and Pb are significantly soluble in tin at room temperature. This is the basis for the removal of insoluble impurity elements by liquation. However, the liquation products have high tin contents, making costly recovery processes necessary.

In pyrometallurgical tin refining, the individual impurities are removed stepwise in batch processes. The use of the time-consuming operations is justified by their high selectivity.

Proposed continuous processes have not been operated on an industrial scale.

5.1. Pyrometallurgical Refining

5.1.1. Removal of Iron

The process for removing iron is based on the temperature dependence of the solubility of iron or Sn – Fe mixed crystals in tin. Accurate experiments have shown that the solubility of iron in tin at 250 °C is 0.0058 wt % [81]. In industrial practice, even lower figures are achieved, which can only be explained by other impurities, such as Cu, As, or Sb, causing deviations from ideal solubility behavior. On cooling molten crude tin,

α-Fe, γ-Fe, FeSn, and $FeSn_2$ precipitate successively. The density of the precipitated compounds is almost the same as that of the molten tin. In practice, "poling", i.e., passing steam or air into the melt, is used to coagulate the precipitated particles, which rise to the surface of the bath and are removed from the molten tin by filtration through graphite, slag wool, or a slab made of silica and limestone chippings. This should be carried out just above the melting point of tin, or in practice at a temperature not less than 260 °C. The process is sometimes carried out in two stages. Iron contents of 0.003 –0.01 wt % can be achieved.

As Ni, Co, Cu, As, and Sb form intermetallic compounds with each other as well as with Fe, these impurities are also removed to some extent.

The treatment of the recovered intermetallic compounds is very complex, as these are in the form of a slurry with large amounts of adhering molten tin. The iron content is only a few per cent, i.e., considerably less than that of the intermetallic compound $FeSn_2$.

The metal slurry is treated in small liquation furnaces. A controlled temperature increase over the range 230 – 300 °C enables pure tin to be removed, and a residue containing ca. 15 % Fe suitable for use in the primary smelting stage to be obtained.

In high-capacity tin smelting works, high-temperature centrifuges are used. These enable a solid residue containing up to 25 % Fe to be obtained [83].

5.1.2. Removal of Copper

After iron has been removed by liquation, the copper content is up to 0.01 %. Elemental sulfur (2 – 5 kg/t) is stirred in at 250 – 300 °C, enabling copper contents as low as 0.001 % to be attained. The resulting copper dross can be removed from the process after several stages of enrichment.

5.1.3. Removal of Arsenic

After removal of iron by liquation, the arsenic content is ca. 0.1 %, significantly higher than permitted levels. For example, the commonly used Sn 99.75 grade should contain < 0.05 % As according to DIN 1704.

Arsenic can be removed from the melts along with some Cu, Ni, and residual Fe by forming intermetallic compounds with aluminum. For this, the aluminum must be present as an ideal solution in the tin. For this reason, the melt must be heated to a temperature close to the melting point of aluminum before the aluminum is added. Special precautions are necessary, e.g., operation in a closed vessel so that the aluminum does not burn on the surface of the bath. The amount added must be approximately three times the stoichiometric amount. The use of Al – Sn master alloys enables the operation to be carried out at a lower temperature. Intense agitation if followed by a settling process with cooling to 350 – 400 °C, and the Al – As mixed crystals can then be removed. Separation of the Al mixed crystals is assisted by poling.

With correct operation, As contents of < 0.02 % can be achieved, i.e., below the permitted level for Sn 99.90 %. This process enables Sb contents of 0.005 %, Cu contents of 0.02 %, and Ni contents of 0.005 % to be attained, and any remaining Fe to be removed.

Any aluminum remaining in the molten tin can be removed by adding sodium, sodium hydroxide, chlorine, or steam, and residual sodium by adding sulfur.

The storage, transport, and treatment of the Al – As product presents problems. Contact with water must be avoided as this leads to the formation of highly toxic arsine and stibine. The material is stored in closed vessels and is converted into a safe product as soon as possible by oxidative roasting or by treating with alkali solution and collecting and burning the liberated arsine to form As_2O_3 and H_2O. The residues obtained both from the roasting and the leaching processes can be recycled to the process.

The large differences in vapor pressure between the impurities (arsenic, antimony, bismuth, and lead) and tin enable selective evaporation at reduced pressure to be used. However, numerous proposed processes have resulted in only two industrial applications.

In a system tested in Russia, the impure tin flows from the top of a vertical reactor under a vacuum of 1 Pa into heated evaporating dishes. The evaporated impurities are collected in a separate chamber. Barometric valves are used to remove the purified tin and the condensate.

In the Bergsöe – Redlac system, a cylinder, cooled on the inside, rotates in a horizontal vacuum chamber above the melt, and the vaporized impurities are deposited on this in solid form. In the next stage of the process, they are scraped off and removed. The results of the vacuum distillation process depend on the reaction temperature and time. The high energy requirement for heating and for producing the vacuum, 400 – 700 kW · h/t tin, is a disadvantage. Moreover, significant quantities of tin are vaporized. The use of selective evaporation of typical impurities in crude tin always involves a compromise between the purity and tin yield. Practical experiments are described in [85].

5.1.4. Removal of Lead

If the lead content is still not low enough after the first stages of the refining process, the lead can be converted into its dichloride by treatment with chlorine, tin dichloride, or tin tetrachloride:

$$SnCl_2 + Pb \rightleftharpoons PbCl_2 + Sn$$

The equilibrium is shifted to the right at low temperatures, so that the process must be carried out at a temperature only a little above the melting point of tin. The process also removes any remaining zinc and aluminum.

The best results are obtained by using two-stage operation, i.e., the product of the second stage, with a reduced lead content, is returned to the first stage. Precise control of the operation can lead to final lead contents of 0.008 wt %.

5.1.5. Removal of Bismuth

In analogy to the thermal refining of lead, bismuth can be precipitated as an intermetallic compound by adding calcium or magnesium. The molar ratio Ca/Mg should be ca. 2 to obtain the best results [46]. A ternary compound is probably formed at this ratio. Under production conditions, scrap magnesium is used, as this is the most economic material.

Final bismuth contents of 0.06 – 0.003 wt % have been reported for full-scale plant. In analogy to a technique used when removing arsenic from aluminum, the calcium and magnesium remaining in the tin can be converted to their chlorides and removed, e.g., by treatment with ammonium chloride.

5.2. Electrorefining

The theoretical conditions for the electrorefining of tin are favorable. The position of tin in the electrochemical series of the elements in aqueous solution show that Au, Ag, Cu, Bi, As, and Sb do not go into solution under electrorefining conditions, but will appear in the anode slime. The elements Ni, Fe, Zn, and Al can be largely removed by a preliminary pyrometallurgical refining operation. Only lead lies close to tin in the electrochemical series. The high electrochemical equivalent weight of tin also favors the use of an electrometallurgical refining process. However, there are considerable problems in the practical realization of the process.

Simple and cheap electrolytes such as solutions of sulfate or chloride lead to spongy or needle-like deposits, and these effects are only slightly moderated by extremely large additions of colloidal materials. The process can only be operated at low current densities, leading to low process rates and inefficient utilization of energy (e.g., low current yields). Also, the presence of large amounts of expensive metal tied up in the process is undesirable economically.

These negative aspects mean that electrorefining is only worthwhile if the tin contains high concentrations of noble metals.

Electrorefining can be carried out in acid or alkaline medium.

5.2.1. Electrorefining in Acid Medium

When sulfate electrolytes are used, additions of chloride, fluoride, crude cresol, glue, nicotine sulfide, α- and β-naphthol, diphenylamine, phenol, and/or cresolsulfonic acid are made. The sulfate ions cause the anodically dissolved lead to go into the anode slime in the form of lead sulfate. Also, sulfides such as nicotine sulfide can lead to the formation of lead sulfide, which is deposited in the anode slime. The organic sulfonic acids prevent the formation of basic tin salts on the anodes.

In spite of these precautions, the formation of coatings on the anode is the main problem in the electrolytic refining of tin in an acid medium. The main cause of coating formation is the lead content of the anodes, which must be removed mechanically when the bath voltage increases. The following operational data are quoted:

Anode mass:	100 – 200 kg
Anode thickness:	30 mm
Cell dimensions:	3.0 – 4.5 m long, 1.0 – 1.2 m wide, 1.0 – 1.5 m deep
Cell construction:	wooden cells with lead cladding or concrete
Cathode replacement:	after 6 d
Anode replacement:	after 10 – 12 d
Anode composition:	94 – 96 % Sn
	0.01 – 0.03 % Fe
	0.3 – 1.3 % Pb
	0.1 – 0.6 % Cu
	0.1 – 3.5 % Bi
	0.02 – 0.35 % As
	0.1 – 0.25 % Sb
	100 – 300 g/t Ag
	0.3 – 0.7 g/t Au
Cathodes:	starter sheets of pure tin

The current yield is largely determined by the rate of removal of anode passivation. The energy consumption is 150 – 200 kW · h/t tin. Because iron accumulates in the electrolyte, regeneration of the electrolyte is necessary.

5.2.2. Electrorefining in an Alkaline Medium

In alkaline medium, i.e., in NaOH or Na_2S electrolytes, less pure anodes (75 % Sn) can be used than are used in an acid medium. A smooth deposit can be obtained without addition of colloids. However, current densities are very low, and the process must be carried out at 90 °C.

Detailed information about the possibilities and limitations of electrorefining, deposition behavior, deposition mechanism, and effects of additives to the electrolyte, pH, and impurities are given in [4].

5.2.3. Other Methods of Electrorefining

Many attempts have been made to use molten salt electrorefining to overcome the disadvantages of electrorefining in aqueous solutions. The electrolyte was molten $CaCl_2$ – KCl –NaCl. Various grades of crude tin were used. The electrodes consisted of graphite crucibles and graphite rods. The operating temperature was ca. 650 °C, and the current density 50 –200 A/dm^2. Arsenic was effectively removed (reduced from 1.5 wt % to 0.005 wt %), and the antimony content was reduced from 0.32 wt % to 0.01 wt %. It proved impossible to scale up from pilot scale to full scale operation, mainly because of problems in the control of the high-temperature process [77].

6. Recovery of Tin from Scrap Materials and Residues [1–3], [5], [11], [86], [87]

Scrap materials and residues which are produced during the processing of metals to give semifinished and finished products are usually known as "new scrap," while the returned old material from industry, trade, building construction, factories, and consumption is known as "old scrap." The use of old and new scrap supplements primary production. It is collected by scrap merchants who work directly with the smelters. Also, in the neighborhood of metal smelting works there are often small scrap metal operations which sort, separate, refine and blend with primary metals to produce a primary metal that corresponds to the standard specification of an original metal [87].

The recovery of tin from tinplate is becoming increasingly difficult, as the change to electrolytic methods of tinning is leading to very thin coatings which sometimes diffuse into the steel sheet. The recycling of this material will continue to be a technically and economically difficult task. Two processes are used for recovering tin from tinplate: the alkaline electrolytic method and the alkaline chemical method.

In the alkaline electrolytic detinning of tinplate, baskets of cleaned scrap are immersed in hot 5 – 10 % sodium hydroxide solution. The baskets form the anodes, and the tinned steel sheet forms the cathodes. The tin is deposited in the form of a sponge. As contact with atmospheric carbon dioxide cannot be prevented, sodium carbonate is formed, and the electrolyte bath must be frequently regenerated. The lacquer coating on the scrap tinplate is removed by adding solvents to the bath or by a special

pretreatment process. The bath is operated at a temperature of 65 – 75 °C, a voltage of 1.5 V, and a cathode current density of 300 A/m^2.

In the alkaline chemical detinning of tinplate, the scrap material in perforated containers is immersed in sodium hydroxide solution. Hydrated sodium stannate is formed according to the equation

$$Sn + 2\,NaOH + 4\,H_2O \rightarrow Na_2SnO_3 \cdot 3\,H_2O + 2\,H_2$$

The hydrogen liberated must be reacted with an oxidizing agent; sodium nitrate is suitable. The dissolution process is accelerated by motion of the container in the liquor. The detinning time is 2 – 4 h, depending on the concentration and the temperature. If sodium nitrite is used instead of sodium nitrate, the tin goes into solution, the foreign metals, e.g., lead, iron, and antimony, can be precipitated, e.g., by hydrogen sulfide, and the tin can then be recovered by electrowinning.

Processing tin-containing alloys is easier than recovering tin from scrap tinplate. However, the tin content of many alloys has decreased over recent years, and alloys have in some cases been replaced by cheaper materials. Both these developments have tended to limit the potential for recovering secondary tin, and also explain why the amount of recovered tin in Europe has decreased from 15 800 t in 1980 to 13 300 t in 1990. In the United States, the amounts of recovered tin have remained almost constant at 16 900 t in 1980 and 17 100 t in 1990 [9].

The quantification of tin recovery from secondary raw materials is difficult because most of it is obtained from scrap alloy.

In addition to the tin concentrates treated in the primary smelting process, there are also other materials that must be treated, including the slags (see Section 4.3.4), oxidic flue dusts, ash, and sweepings containing very variable amounts of tin. Tin-containing processing scrap is also produced during casting, metal forming and cutting, tinning, and alloying. Considerable amounts of recycled scrap also come from the manufacture of cans, tinplate, tubes, foil, pure tin articles, and alloys such as solders, antifriction and bearing metals, type metal, etc.

In recycling it is essential to sort tin-containing materials into standard grades with exact analytical specifications so that the metallurgical process can be optimized.

Short drum furnaces are suitable for processing oxidic materials, although shaft kilns and reverberatory furnaces are also used. The reduction is performed by coke/coal, with added sodium carbonate or fluorspar as flux. The process is operated in one or two stages, depending on the material. Scrap alloys containing high proportions of lead, antimony, or copper are remelted to form alloys. Scrap babbitt (bearing metal) contains zinc, which is either removed in the slag or selectively volatilized. Scrap solder alloys are refined like crude tin.

7. Analysis [88]

7.1. Analysis of Ores and Concentrates

Determination of Sn. In the determination of tin in ore concentrates, the choice of method depends on the presence or absence of typical impurities.

Tungsten-Free Ores and Concentrates. After fusion with sodium peroxide and dissolution in water, the solution obtained is acidified with hydrochloric acid and partially evaporated to drive off arsenic. The antimony is then precipitated with iron powder (cementation). The tin in the filtrate can then be "cemented" by adding aluminum powder, and determined by iodometric titration.

Tungsten-Containing Ores and Concentrates. The tungsten can be precipitated from the acidified solution by adding cinchonine. The excess of this reagent in the filtrate is decomposed by fuming with sulfuric acid. The solution is then taken up in hydrochloric acid and treated as in the determination of tin in tungsten-free ores.

Silicate-Containing Ores and Concentrates. The material is boiled to dryness with nitric acid, and the residue is then strongly heated, fumed with HF/H_2SO_4, and fused with sodium peroxide. The tin determination can then be carried out as for tungsten-free materials.

Determination of Other Elements. The determination of tungsten is carried out by precipitating with cinchonine after the fusion stage. The precipitate is strongly heated (ca. 750 °C) to form WO_3, and tungsten is then determined gravimetrically.

Arsenic is determined by distilling it out of the acidified solution of fused product and then carrying out a bromatometric titration on the distillate.

Antimony is determined by adding iron powder to the acidified fusion product to precipitate antimony sponge. This is dissolved in Br_2/HCl, and any arsenic still present is driven off by evaporating with HCl. The antimony is purified by reprecipitation, and determined by bromatometric titration.

For the determination of other elements such as cadmium, iron, nickel, copper, bismuth, lead, zinc, and the noble metals, it is best to remove zinc, arsenic, and antimony from the dissolved product of a sodium peroxide fusion (acidified with HCl) by evaporating with Br_2/HBr. The elements can be determined in the solution by atomic absorption spectrometry.

To determine sulfur, the sample is heated in a stream of oxygen, the SO_2 formed is collected in a dilute solution of H_2O_2, and the H_2SO_4 formed is determined by titration. The sulfur content of the tin is calculated from this.

7.2. Analysis of Metallic Tin

The preferred methods of analysis of pure and commercial-grade tin are detailed in DIN 1704 [88].

Arsenic is determined by dissolving the metal in a strongly acidic solution of $FeCl_3$. The $AsCl_3$ formed is distilled off, and can be determined photometrically by the molybdenum blue method.

Antimony is determined by dissolving the metal in concentrated sulfuric acid. After adding hydrochloric acid, the antimony is oxidized with cerium(IV) to antimony(V). This is then extracted with isopropyl ether and can be determined photometrically as yellow potassium tetraiodoantimonate.

Lead is determined by dissolving the metal in a mixture of Br_2, HBr, and $HClO_4$, fuming this to volatilize the zinc, removing any Tl that might still be present by extraction with isopropyl ether, and determining the lead by polarography.

In the determination of copper, the initial dissolution is similar to that used in the determination of lead. The copper in the solution then is determined photometrically as the diethyldithiocarbamate complex after extraction with CCl_4.

The determination of zinc also requires a dissolution process similar to that for lead. The solution is acidified with hydrochloric acid, and heavy metals still present are precipitated as sulfides. The zinc in the filtrate obtained can be determined by polarography.

Iron is determined by first carrying out the dissolution and precipitation of heavy metals as for zinc determination. The iron in the filtrate can be determined photometrically as the sulfosalicylic acid complex.

The determination of aluminum also requires dissolution and removal of heavy metals by precipitation of their sulfides as for iron determination. The aluminum in the filtrate can be determined photometrically as the eriochrome cyanine complex.

As well as the analytical methods recommended in DIN 1704, rapid and efficient methods such as atomic absorption spectrometry (AAS) and atomic emission spectrometry with inductively coupled plasma excitation (ICP-AES) are also being used to an increasing extent [89]. These methods are specified in the German and international standards for the analysis of water, wastewater, and sewage sludge.

After dissolution of the tin in a mixture of Br_2, HBr, and $HClO_4$, the accompanying antimony, arsenic, bismuth, copper, iron, lead, aluminum, cadmium, and zinc can be determined with a high degree of accuracy in the presence of each other, without first separating them, by means of AAS and ICP-AES. In the determination of arsenic and antimony, other dissolution processes must first be performed. The analysis of metallic tin and tin alloys is often carried out by spectral analysis with spark or arc excitation, and the analysis of tin slags and concentrates by X-ray fluorescence analysis.

8. Economic Aspects [2], [9], [11]

The amounts of tin mined, smelted, and consumed in the years 1980 – 1990 are given in Table 5.

Even in 1938, smelting production amounted to 171 200 t [3], and this had increased by only 66 500 t or 38.8 % in 1990. This is an average increase of 9.75 % per annum.

Table 5. World production and consumption of tin (in 10^3 t)

Year	Mining output	Smelting output	Consumption
1980	235.5	243.6	221.4
1985	185.3	216.2	214.3
1990	210.7	225.6	232.7

Typically in the production and consumption of tin, the production processes of mining and smelting are geographically remote from the places where the metal is consumed.

The main producers, i.e., Brazil, Indonesia, Malaysia, Bolivia, and to some extent China, consume very little tin themselves (see Table 6). On the other hand, the United States, Japan, Germany, and the United Kingdom produce little or no primary tin themselves and are the main tin consumers. In the CIS, production and consumption are approximately equal.

Table 6. Mining output and consumption of tin in various countries 1990 [9]

Country	Mining output		Consumption	
	in 10^3 t	as %	in 10^3 t	as %
Brazil	39.1	18.6	6.1	2.6
Indonesia	37.1	15.1	1.4	0.6
Malaysia	28.5	14.3	3.3	1.4
Bolivia	17.3	8.2	0.4	0.2
China	35.8	17.0	18.0	7.7
Russia (CIS)	13.0	6.1	20.0	8.5
United States	0.1	0.04	37.3	16.0
Japan			33.8	14.5
Germany			19.3	8.2
United Kingdom	3.4	1.6	10.4	4.3

The continuous fall in the price of tin (> 30 000 DM/t in 1985, ca. 10 000 DM/t in 1990) has led to many casualties worldwide. The worst effects have been in Malaysia, where over 80 suppliers have been closed down. In 1980, Malaysia was the main producer of tin, with a mine output of 61 000 t. This fell to 28 500 t in 1990, and Malaysia now produces less tin than Brazil, China, or Indonesia. Even the well-known tin smelter Capper Pass in the United Kingdom has ceased production, as have the tin mines in the Altenberg region of Saxony.

9. Tin Alloys and Coatings [1], [2], [11]

Tin is one of the most important constituents of low-melting nonferrous alloys. The following important properties of the metal are exploited

1) Low melting point
2) Low hardness
3) Good wetting properties
4) Effective incorporation of foreign particles
5) Good compatibility with foodstuffs

Tin utensils have been produced for over 5000 years, and well-preserved examples exist from the various epochs.

Tin utensils are always made of tin alloys, as the pure metal is too soft. The most important alloying elements are antimony, copper, and lead. The tin is usually melted first, and it then readily forms alloys with pure metals, which have good solubility properties. To minimize burning, especially of antimony, master alloys are usually used.

As tin has good flow and casting properties, casting is the most important method of producing tin articles. All the processes used in a modern foundry are suitable. Those most often used are sand, shell, centrifugal, and pressure die casting. The casting methods are sometimes automated, whereby the low casting temperatures make small demands on the material used for the shells and molds.

As very thin-walled cast tin cannot always be produced, pressure forming methods are now also widely used. For example, a circular sheet can be spun over a former. This method is especially suitable for simple rotationally symmetrical items without asymmetrical surface effects.

Owing to the good forming properties of tin, other methods can also be used. For example, stamping and extrusion present no special problems, and individual items can be produced by forging and hammering processes.

The composition of the metal used to produce tin articles is specified in DIN 17 810 and the materials regulation RAL-RG 683. The DIN 17 810 specification is as follows:

Grade	Sn 90-10
Material no.	2.3710
Tin	min. 90 %
Antimony	$\leq$ 7 %
Copper	$\leq$ 3 %
Silver	$\leq$ 4 %
Lead	max. 0.5 %
Sum of others	0.3 %

The lead limit of 0.5 % is imposed merely because this is technically feasible. It has been

shown that a lead content of 2 % leads to insignificant releases of lead even after utensils have been kept at unusually high temperatures and for unusually long periods of time.

Solders. Most solders are based on the tin – lead binary system (→ Lead Alloys, Chap. 5.), which has a eutectic at ca. 63 % tin and 183 °C. The solid solubility of 1 – 2 % lead in tin and 13 % tin in lead is not relevant to production conditions.

In solder applications, it is of great importance to know what percentage of impurities can cause problems, and, conversely, whether alloying elements can have a detrimental effect on soldered joints under certain conditions. This question is extremely important in the electronics industry because of the small amounts of solder used in a soldered joint, and the small distances between the soldered joints. The state of knowledge is as follows [11, Chap. 5.8]:

Zinc:	Visible impairment of the surface of the solder by oxide formation at 0.005 %. Recommended limit: 0.001 %.
Aluminum:	Impairment of adhesive bond, hot brittleness, and dull appearance at 0.005 %. Recommended limit: 0.001 %.
Phosphorus:	Increased oxidation at 0.001 %. Lower concentrations reduce oxidation in unstirred baths.

It is known that other elements, such as arsenic and sulfur, can have detrimental effects, but precise quantitative experimental results are not available.

Low friction materials and bronzes have the following useful properties:

1) High mechanical strength with good electrical conductivity
2) Good soldering properties
3) Extremely good properties as a bearing (antifriction) metal
4) Good machinability at room temperature
5) Good general corrosion resistance towards the atmosphere and seawater, and, in the case of zinc-free alloys, towards stress corrosion

Apart from cast articles, the most important forms are wire, rolled profile, sheet, and strip. The material is also used in bearings and in the chemical industry. Its use in domestic items, e.g., fittings and mountings, is also considerable. The alloys are classified as casting alloys and wrought alloys, the latter having lower tin contents. Some important copper – tin alloys, as specified in DIN 1705/1716, are listed in the following:

Gunmetal	
G-Cu Sn 12	88 % Cu, 12 % Sn
G-Cu Sn 12 Ni	86 % Cu, 12 % Sn, 2 % Ni
G-Cu Sn 12 Pb	86 % Cu, 12 % Sn, 2 % Pb
Red bronze	
G-Cu Sn 10 Zn	88 % Cu, 10 % Sn, 2 % Zn
G-Cu Sn 7 Zn Pb	83 % Cu, 7 % Sn, 4 % Zn, 6 % Pb
Leaded bronze	
G-Cu Pb 5 Sn	85 % Cu, 5 % Pb, 10 % Sn
G-Cu Pb 15 Sn	77 % Cu, 15 % Pb, 8 % Sn
G-Cu Pb 22 Sn	76 % Cu, 22 % Pb, 2 % Sn
Wrought alloys	
Cu Sn 2	98 % Cu, 2 % Sn
Cu Sn 6	94 % Cu, 6 % Sn
Cu Sn 6 Zn	88 % Cu, 6 % Sn, 6 % Zn

Although the copper – tin alloys are some of the oldest materials used by humans, their development is not yet exhausted even today.

The most important development aims are improvement of mechanical properties and corrosion resistance, and reduction of the tin content.

Sintering Metallurgy of Bronzes. An interesting new use for tin is as an addition in powder form when sintering bronze. Especially when this is for use as a bearing metal, economic advantages are obtained by the addition of 4 % tin to the copper powder with or without lead addition.

Low-melting alloys are of great importance in several technical applications. Their melting points usually lie significantly below 150 °C. Bismuth is always an essential alloy constituent.

Their most important application areas are in mold making, safety systems for the prevention of fire and overheating, and stepwise soldering.

Melting points, compositions, and areas of use of typical low-melting alloys are listed in Table 7.

Amalgams. Tin has been used for dental fillings since the Middle Ages, and amalgams since the 1800s. Subsequent developments have led to the silver – tin amalgams used today (→ Dental Materials, Chap. 2.3.2.). A typical amalgam has

Table 7. Melting points, compositions, and applications of typical low-melting alloys

Melting point, °C	Typical composition, wt %					Applications
	Bi	Sn	Pb	In	Cd	
47	44.7	8.3	22.6	19.1	5.3	test castings, fixing lenses
58	49.0	12.0	18.0	21.0		fixing components
70	49.4	12.9	27.7		10.0	supporting components
70 – 73	50.0	13.3	26.7		10.0	tube bending, radiation protection, fixing components
96	52.0	16.0	32.0			temperature fuses
138 – 170	40.0	60.0				accurate molds, cores, gravity die casting

the following composition: 52 % Hg, 33 % Ag, 12.5 % Sn, 2 % Cu, 0.5 % Zn.

When the mixture of metals is ground together, the following hardening reaction takes place:

$$AgSn_3 + 4\,Hg \longrightarrow Ag_2Hg_3 + Sn_{7-8}Hg + Ag_3Sn$$

The metallographic structure of a dental amalgam consists of islands of solid undissolved particles of alloy (Ag_3Sn) in a soft matrix of silver and tin amalgams.

Alloy Coatings. Tin alloys are important in the production of coatings by electroplating and hot tinning. The most important of these are tin – zinc, tin – nickel, tin – cobalt, and tin – copper.

Tin – lead coatings are mainly used for corrosion protection and as a preparation for soldering. Electrolytically applied coatings must be treated with hot palm oil or by infrared heating. This melts the coating and can prevent the formation of whiskers.

Tin – zinc coatings are increasingly replacing the toxic cadmium coatings.

Tin – nickel and tin – cobalt coatings are mainly used in electrical installations, e.g., to produce electrical connectors.

Additions to Alloys. Tin is increasingly used as an alloy addition in the steel industry. The addition of 0.1 – 0.5 % tin causes cast iron to solidify with a pure pearlitic structure, making it uniformly hard and wear-resistant.

Sinter Metallurgy. In the sinter metallurgy of iron, addition of 2.5 – 5 % of a tin – copper alloy (2 : 3) gives reduced sintering temperatures and times, and in particular improves the dimensional accuracy of the sintered components.

10. Inorganic Tin Compounds

Consumption of inorganic tin compounds is lower than that of organic tin compounds, but they are often the starting materials used to produce the organic tin compounds.

In minerals, tin is nearly always tetravalent and bonded to oxygen or sulfur. The only exception is herzenbergite, SnS, in which it is divalent.

In industry, tin(II) and tin(IV) compounds are produced from metallic tin. Many tin(II) compounds which are sufficiently stable for practical purposes have a strong tendency to change into tin(IV) compounds and are therefore strongly reducing. For example, $SnCl_2$ precipitates gold and silver in metallic form from their salt solutions.

The salts in both valency states hydrolyze in aqueous solution to form insoluble salts. In alkaline media, stannites (divalent) and stannates (tetravalent) are formed.

10.1. Tin(II) Compounds

Tin(II) chloride, $SnCl_2$, is the most important inorganic tin(II) compound. It is produced on an industrial scale by reducing tin(IV) chloride with molten tin, or by direct chlorination of tin.

Solutions of tin(II) chloride are obtained by dissolving metallic tin in hydrochloric acid, or by reducing a solution of $SnCl_4$ with metallic tin.

The anhydrous substance is white, has a greasy luster, and dissolves readily in water, alcohol, ethyl acetate, acetone, and ether. The clear, nondeliquescent, monoclinic dihydrate, $SnCl_2 \cdot 2\,H_2O$, crystallizes from aqueous solution and is the commercial product.

On dilution, the aqueous solution becomes cloudy as hydrolysis causes precipitation of the basic salt:

$$SnCl_2 + H_2O \rightleftharpoons Sn(OH)Cl + HCl$$

The cloudiness can be prevented by small additions of hydrochloric acid, tartaric acid, or ammonium chloride. Because of its strong tendency to hydrolyze, the dihydrate can only be dehydrated over concentrated sulfuric acid or by heating in a stream of hydrogen chloride.

Tin(II) chloride is an important industrial reducing agent, being used to reduce aromatic nitro compounds to amines, aliphatic nitro compounds to oximes and hydroxylamines, and nitriles to aldehydes.

Tin electroplating can be carried out in a fused eutectic salt mixture of 20 % $SnCl_2$ and 80 % KCl at 200 – 400 °C [90], [91].

Tin(II) Oxide Hydrate and Tin(II) Oxide. If aqueous solutions of $SnCl_2$ or other tin(II) salts are reacted with alkali metal carbonate or ammonia, an amorphous white precipitate of tin(II) oxide hydrate, $5\,SnO \cdot 2\,H_2O$, is obtained [92]. $Sn(OH)_2$ does not exist. Tin(II) oxide hydrate is amphoteric. Dehydration in a stream of carbon dioxide gives tin(II) oxide. Tin(II) oxide hydrate and tin(II) oxide are starting materials for the production of other tin(II) compounds.

Other Tin(II) Compounds.

Tin(II) fluoride, SnF_2, is formed from tin(II) oxide hydrate and hydrofluoric acid, and is added to toothpastes as an anticaries agent.

Tin(II) fluoroborate hydrate, $Sn(BF_4)_2 \cdot n\,H_2O$, is formed by dissolving the oxide hydrate or the oxide in aqueous fluoroboric acid. Sulfuric acid reacts with the oxide hydrate or the oxide to form tin(II) sulfate. Both tin(II) sulfate and tin(II) fluoroborate are important in the production of metallic tin coatings by electroplating.

Tin(II) bromide, $SnBr_2$, and *tin(II) iodide*, SnI_2, are produced by reacting metallic tin with the appropriate hydrogen halide.

Tin(II) cyanide, which is produced from bis-(cyclopentadienyl)tin(II) and hydrogen cyanide, is the only known compound of tin with inorganic carbon:

$$(C_2H_5)_2Sn + 2\,HCN \longrightarrow Sn(CN)_2 + 2\,C_2H_6$$

The tin(II) salt of ethylhexanoic acid is an effective catalyst in polyurethane production.

10.2. Tin(IV) Compounds

Tin(IV) Hydride. The toxic, colorless, flammable gas, tin(IV) hydride, is formed by the reduction of tin(IV) chloride by $LiAlH_4$ in diethyl ether at −30 °C. It is stable for several days at room temperature, and decomposes into its elements at 150 °C in the absence of air, forming a tin mirror.

Tin(IV) Halides and Halostannates(IV). Anhydrous tin(IV) chloride is a colorless liquid which fumes strongly in air. It is a good solvent for sulfur, phosphorus, and iodine, and is miscible in all proportions with carbon disulfide, alcohol, benzene, and other organic solvents. It hydrolyzes in water, evolving much heat and forming colloidal tin(IV) oxide and hydrochloric acid:

$$SnCl_4 + 2\,H_2O \longrightarrow SnO_2 + 4\,HCl$$

In moist air, the pentahydrate, $SnCl_4 \cdot 5\,H_2O$, is formed, the so-called butter of tin, a white deliquescent crystalline mass with a melting point of 60 °C. In industry, $SnCl_4$ is produced by the reaction of chlorine with tin. The anhydrous product is obtained if the metal is covered with $SnCl_4$. Anhydrous tin(IV) chloride is an important starting material for the production of organic tin compounds (see Sections 11.2 and 11.3).

Tin(IV) bromide, $SnBr_4$, and tin(IV) iodide, SnI_4, are also obtained by the reaction of metallic tin with the halogens. Tin(IV) fluoride is produced by the reaction of tin(IV) chloride with anhydrous hydrogen fluoride:

$$SnCl_4 + 4\,HF \longrightarrow SnF_4 + 4\,HCl$$

Tin(IV) halides react readily with metal halides to form the halostannates(IV), the coordination number of the tin increasing from four to six. The reaction proceeds as follows (X = halogen):

$$SnX_4 + 2\,MX \rightleftharpoons M_2SnX_6$$

One of the best known compounds of this type is ammonium hexachlorostannate, $(NH_4)_2SnCl_6$, the so-called pink salt.

Hexachlorostannic acid, $H_2SnCl_6 \cdot 6\,H_2O$, is formed by passing HCl into a concentrated solution of $SnCl_4$.

Tin(IV) Oxide, Tin(IV) Oxide Hydrate, and Stannates(IV). Tin(IV) oxide decomposes above 1500 °C without melting to form tin(II) oxide:

$$2\,SnO_2 \longrightarrow 2\,SnO + O_2$$

Pure tin(IV) oxide can be obtained by the combustion of powdered tin or sprayed molten tin in a hot stream of air. It is insoluble in acids and alkalis. Specially prepared tin(IV) oxide has many uses, total world consumption of this material being > 4000 t/a. It is used in combination with other pigments to produce ceramic colorants. It has a rutile structure, and hence can absorb the colored ions of transition metals. The products obtained form the basis of ceramic colors, and include tin vanadium yellow, tin antimony gray, and chrome tin pink. The thermal stability of the tin colors enables them to be used both in and under the glaze.

Electrodes made of SnO_2 are used in the production of lead glass [93]. They are resistant to corrosion by molten glass, and have good electrical conductivity when hot.

Coatings of tin(IV) oxide treated with indium oxide (<100 µm thick) give good transparency properties to aircraft window systems, increase their strength, and give protection from icing.

If tin(IV) oxide is reacted with a solution of alkali, or a solution of stannate is reacted with acid, a white, gel-like precipitate of tin(IV) oxide hydrates is formed which are very soluble in alkalis and acids. This precipitate was formerly known as "α-stannic acid", and the aged product, which is sparingly soluble, as "β-stannic acid" (metastannic acid). Today, this product is regarded as tin(IV) oxide hydrate with the formula $SnO_2 \cdot n\,H_2O$, where n decreases with aging.

The reaction of powdered or granulated tin with concentrated nitric acid leads to the formation of the reactive β-tin(IV) oxide hydrate. This can be used as a catalyst for aromatics.

The β-tin oxide hydrate gels precipitated from $SnCl_4$ by ammonia and then dried are stable towards nuclear radiation, and can be used in chromatographic columns for separating radioactive isotopes [94].

Fusion of tin(IV) oxide with alkali metal hydroxides leads to formation of alkali metal hexahydroxystannates according to the following reaction scheme (M = alkali metal):

$$SnO_2 + 2\,MOH + 2\,H_2 \longrightarrow M_2\,[Sn(OH)_6]$$

The sodium and potassium complexes are used as alkaline electrolytes in electrolytic tin plating.

Tin(IV) sulfide, SnS_2, is formed as golden yellow flakes with a hexagonal crystal structure by passing hydrogen sulfide through a weakly acidic solution of a tin(IV) salt. On heating, the crystals become dark red to almost black, reverting to yellow on cooling.

The tin disulfide known as "mosaic gold" is produced industrially by heating tin amalgam with sulfur and ammonium chloride. It is used for gilding picture frames, and in painting to produce deep yellow to bronze color shades.

11. Organic Compounds of Tin [3], [95], [96]

The organic chemistry of tin has attracted major interest since 1945. The first organotin compounds were prepared in 1849 by Frankland and in 1852 by Löwig [97]. In the first technical application in 1936, the discovery of the stabilizing effect of these compounds on poly(vinyl chloride) was utilized. The biocidal properties of other organotin compounds have been known since ca. 1950.

Only the organic compounds of tetravalent tin are used in industry.

Most organotin molecules contain a single tin atom with 4 substituents. They are classified according to the number of direct tin-carbon bonds: R_4Sn, R_3SnX, R_2SnX_2, $RSnX_3$.

Here, R denotes any hydrocarbon group and X denotes a group such as a halide, OH, OR, SR, acid group, etc. Most of these compounds are colorless liquids at room temperature or slightly above. They are very soluble in organic solvents but sparingly soluble in water.

Organotin compounds have a very wide range of applications, depending on their type, including the stabilization of PVC, catalysis, crop protection, and wood preservation. Also, for some time, various organotin compounds have been increasingly used as laboratory chemicals, especially organotin alkoxides and hydrides. These are used as synthesis auxiliaries and as mild and selective reducing agents.

Organotin compounds do not occur in nature.

11.1. Properties of Organotin Compounds

Under the influence of light, atmospheric oxygen, or certain microorganisms, organotin compounds are degraded in a relatively short time, the hydrocarbon groups being split off to leave behind nontoxic inorganic products. Although both the tin – carbon bond (average dissociation energy 209 kJ/mol) and the tin –oxygen bond (average dissociation energy 318 kJ/mol) are reactive, they are sufficiently stable for general handling purposes.

The symmetrical tetraalkyltin compounds have a very slight odor. They are colorless, form monomolecular solutions, are fairly stable towards water and air, and can be distilled without decomposition at $< 200\,^{\circ}C$. Their solubilities and boiling points are similar to those of the branched chain paraffins with similar molecular mass; the higher homologues are waxy substances.

The symmetrical tetraaryltin compounds are stable towards air and water and are also colorless. They melt at temperatures above 150 °C.

The organotin hydrides, with the exception of some aryl tin hydrides which are solid at room temperature, are colorless, nonassociated liquids which are rapidly attacked by oxygen and therefore can only be prepared and stored under inert gas. They are important reducing agents.

The organotin fluorides, the diorganotin dihalides, and the aromatic organotin monohalides are solids at room temperature, while the aliphatic organotin monohalides and trihalides are liquids. The higher triorganotin derivatives have a broad biocidal effect on microorganisms such as fungi, bacteria, and harmful waterborne organisms such as algae, tube worms, shellfish, etc. The most active compounds are the tributyl-, trichlorohexyl-, and triphenyltin compounds.

The di- and monoorganotin derivatives in which methyl, butyl, and octyl groups are bonded to the tin stabilize polymers sensitive to light and temperature such as PVC if the tin is bonded via oxygen or sulfur to certain other groups.

11.2. Production of Organotin Compounds

Tetraorganotin Compounds from Tin Tetrachloride and Organometallic Compounds. Tin tetrachloride is the key substance for the production of organotin(IV) compounds. In industry, the tin tetrachloride is first alkylated with organic compounds of magnesium, aluminum, or sodium to form tetraorganotin compounds. The process is usually continuous.

Organotin Chlorides from Tetraorganotin Compounds and Tin Tetrachloride. If tetraorganotin compounds are reacted with stoichiometric amounts of tin tetrachloride, the corresponding organotin chlorides are obtained:

$$SnR_4 + 1/3\,SnCl_4 \rightleftharpoons 4/3\,R_3SnCl$$

$$SnR_4 + SnCl_4 \rightleftharpoons 2\,R_2SnCl_2$$

$$SnR_4 + 3\,SnCl_4 \rightleftharpoons 4\,RSnCl_3$$

The production of triorganotin chlorides and diorganotin dichlorides proceeds smoothly according to this reaction. Monoorganotin trichlorides can only be obtained in a few cases where R = acryl or vinyl and in special solvents or with catalysts.

Direct Synthesis of Organotin Chlorides from Tin. Organotin chlorides can be obtained by direct reaction of tin with unsaturated organic compounds and hydrogen halides (ester tin process) or from organic halides (catalytic direct process).

Ester Tin Process for the Production of Tin Carboxylic Acid Derivatives from Tin. Unsaturated organic compounds, such as esters of substituted or unsubstituted acrylic acid, acrylonitrile, or vinylphosphoric diesters, react with metallic tin and hydrogen chloride in a polar medium (ethanol, concentrated hydrochloric acid, or diethyl ether) to form the so-called ester tin compounds, e.g., bis(2-methoxycarbonylethyl)tin dichloride [98].

Catalytic Production of Organotin Halides from Tin. Organotin halides can be produced discontinuously or continuously from metallic tin and organic halides with the aid of catalysts at elevated temperatures. The most effective of these catalysts are the tetraalkylammonium halides, tetraalkylphosphonium halides, and other derivatives of N, P, As, or Sb.

Production of Organotin Trichlorides by Addition of Tin Dichloride and Hydrogen Chloride. The unsaturated starting compounds suitable for the ester tin process, when reacted with tin(II) chloride and hydrogen chloride, form the corresponding organotin trichlorides, e.g., (2-methoxycarbonylethyl)tin trichloride [99].

Production of Unsymmetrical Organotin Compounds by Addition of Organotin Hydrides (Hydrostannation). Unsymmetrical tetraorganotin compounds that may contain functional or unsaturated groups in the alkyl groups can be synthesized by addition of organotin hydrides to alkenes and alkynes. The reaction is favored by radical formers and UV light.

Conversion of Organotin Chlorides to other Halides or Derivatives with Heteroatoms via Organotin Oxides. The organotin chlorides are quantitatively converted into organotin oxides in alkaline medium:

$$2\,R_3SnCl \longrightarrow (R_3Sn)_2O$$

$$R_2SnCl_2 \longrightarrow 1/n\,(R_2SnO)_n$$

$$RSnCl_3 \longrightarrow 1/n\,(RSnO_{1.5})_n$$

In acid media, many organotin compounds, e.g., fluorides, bromides, iodides, pseudohalides, carboxylates, thiolates, etc., are obtained from the organotin compounds:

$$(R_3Sn)_2 \longrightarrow 2\,R_3SnX$$

$$1/n\,(R_2SnO)_n \longrightarrow R_2SnX_2$$

$$1/n\,(RSnO_{1.5})_n \longrightarrow RSnX_3$$

X = halogen or other functional group

These transformation reactions are of industrial importance, as they enable the sensitive organotin compounds to be converted into organotin oxides that are insoluble in water, stable to air, easily transported, and storable for long periods. These can then be used to produce either the original organotin oxides or other organotin compounds when required.

11.3. Industrially Important Compounds

A few typical examples of the many applications of organotin compounds are described here.

Methyl Compounds. A legally permitted stabilizer for PVC used with foodstuffs is produced from dimethyltin dichloride and methyltin trichloride. It consists of:

$(CH_3)_2Sn[SCH_2COOC_5H_{10}CH(CH_3)_2]_2$	75 %
$CH_3Sn[SCH_2COOC_5H_{10}CH(CH_3)_2]_3$	25 %

Butyl Compounds. Tetrabutyltin, $(C_4H_9)_4Sn$, can be converted to tributyltin chloride, $(C_4H_9)_3SnCl$, and this can be converted to bis(tributyltin) oxide, $(C_4H_9)_3SnOSn(C_4H_9)_3$, by treatment with NaOH. This product, which is insoluble in water and miscible with industrial solvents, is moderately toxic. It is an active biocide with many uses. For example, it is used as an antifouling paint for ships, for the prevention of slimes in industrial recirculating water systems, for combating freshwater snails that cause bilharzia, as a wood and textile preservative, and as a disinfectant.

The readily interconvertible compounds dibutyltin chloride $(C_4H_9)_2SnCl_2$ and dibutyltin oxide $[(C_4H_9)_2SnO]_n$ (a polymeric powder) are the starting substances for the production of the most common PVC stabilizers, i.e., the liquid dibutyltin dilaurate $(C_4H_9)_2Sn(OCOC_{11}H_{23})_2$, the polymeric solid dibutyltin maleate $[(C_4H_9)_2SnOCOCH{=}CHCOO]_n$, the liquid dibutyltin bis(isooctylmaleate) $(C_4H_9)_2Sn[OCOCH{=}CHCOOC_5H_{10}CH(CH)_3]_2$, and the liquid dibutyltin bis(thioacetic acid isooctyl ester) $(C_4H_9)_2Sn[SCH_2COOC_5H_{10}CH(CH_3)_2]_2$.

Octyl Compounds. The stabilizers used in the production of PVC film for the foodstuffs industry, i.e., the liquid octyltin(thio)acetic acid isooctyl esters with the formulas $(n\text{-}C_8H_{17})_2Sn[SCH_2COOC_5H_{10}CH(CH_3)_2]_2$ and $n\text{-}C_8H_{17}Sn[SCH_2COOC_5H_{10}CH(CH_3)_2]_3$ are produced from isooctyl mercaptoacetate and dioctyltin dichloride $(C_8H_{17})_2SnCl_2$ or octyltin trichloride $C_8H_{17}SnCl_3$, respectively.

Cyclohexyl Compounds. Tricyclohexyltin hydroxide $(cyclo\text{-}C_6H_{11})_3SnOH$ is obtained by alkaline hydrolysis of tricyclohexyltin chloride $(cyclo\text{-}C_6H_{11})_3SnCl$. It is a colorless, crystalline substance, insoluble in water, and has a very marked acaricidal action, attacking many mites and acarides, thereby protecting plants and useful insects. It is the main component of the

commercial product Plictran (Dow Chemical), which is used in fruit growing, viticulture, and greenhouses.

Phenyl Compounds. The phenyl derivatives of tin are used as fungicides, e.g., for the treatment of potato rot and leaf spot in root tubers. Typical compounds are triphenyltin hydroxide, $(C_6H_5)_3SnOH$ (Du Ter, Philips-Duphar), and triphenyltin acetate, $(C_6H_5)_3SnOCOCH_3$ (Brestan, Hoechst).

11.4. Analysis of Organotin Compounds

The analysis of organotin compounds is a complex field. Methods used are described in detail in [100].

In the determination of individual organotin compounds by gas chromatography, it is first necessary to convert the organotin halides or oxides into unsymmetrical tetraorganotin compounds by methylation or butylation with Grignard reagents [100].

11.5. Storage and Shipping of Organotin Compounds

Organotin compounds are stored and transported in drums and vessels of steel sheet coated on the inside with a special paint. In the case of solids, the emission of hazardous dust can be prevented by incorporating these products in paste formulations.

11.6. Pattern of Production and Consumption

World production of organotin compounds was ca. 50 t/a in 1950, 35 000 t/a in 1981, and 40 000 t/a in the mid-1990s. The tin content of these materials is ca. 25 %.

In the main producing and consuming areas – United States, Western Europe, and Japan – 76 % of the organotin compounds are used as stabilizers for PVC, 10 % as antifouling biocides, 8 % as agricultural biocides, and 5 % as catalysts for the production of polyurethanes and silicones.

The main producers of organotin compounds are:

United States:	M & T Chemicals, Thiokol-Charstal, and Interstab (Akzo)
Japan	Hokko Chemical Industries, Yoshitomi Pharmaceutical Industries, Nitto Kasei, and Somkyo Organic Chemicals
Europe	Schering, Akzo Chemie, and Ciba-Geigy

12. Toxicology

Metallic tin is generally considered to be nontoxic. As early as the Middle Ages, it was used in the form of plates, jugs, and drinking vessels. Even large amounts of tin salts in the digestive system cause negligible harm. Apparently, tin can migrate only very slowly through the intestinal walls into the blood. Orally ingested tin is poorly resorbed by animals and humans. The half-life in the kidneys and liver is 10 – 20 d, and in the bones 40 – 100 d. Cases of poisoning are almost unknown. Massive inhalation of tin or tin oxide dust by exposed industrial workers can lead to irritation of the respiratory tract. In extreme cases, metal fume fever with similar symptoms to those of "zinc fever" or "brass fever" also occurs. As the peroral ingestion of tin and its inorganic compounds is comparatively harmless because of the relatively low resorption, the limit value for the prevention of sickness and diarrhea for fruit conserves is ca. 250 – 500 mg/kg, and for fruit juices 500 – 1000 mg/kg. In current industrial practice, the tin cans are additionally lacquered, and the tin concentrations in preserved fruit and vegetables are < 250 ppm. The MAK value, calculated as tin and measured in total dust, has been 2 mg/m^3 for many years [101], [102].

Hydrochloric acid formed by the hydrolysis of tin chloride can cause acid burns. Tin hydride is very toxic, having a similar effect on the human organism to arsine [103].

Organotin compounds are very toxic; the MAK value is 0.1 mg/m^3 [102]. These compounds can differ widely in their effects, and can also be slowly converted to other compounds in the organism, so that toxic symptoms can change during the induction time. The toxicity of alkyl and aryl tin compounds decreases in the se-

ries: trialkyl > dialkyl > tetraalkyl > monoalkyl compounds. Whereas tributyl- and triphenyltin compounds are almost as toxic as HCN, the monoalkyl compounds have a toxicity similar to that of the inorganic tin compounds.

The resorption of tin alkyl and tin aryl compounds can have harmful effects on the CNS, such as edema of the brain and spinal cord and damage to the respiratory center. The volatile organotin compounds cause persistent headaches, epileptiform convulsions, narcosis, and respiratory paralysis.

Dibutyltin dichloride, tributyltin chloride, and analogous alkyl tin halides, after a latent period, cause irritation and burning of the skin and especially the mucous membranes, and are intensely sternutatory and lachrymatory [104], [105].

In cases of poisoning by organotin compounds, long-term observation of the functioning of the liver and CNS is necessary.

Abstract

The article contains sections titled:

1. Tire and Vehicle
2. Tire and Road
3. Tire Characteristics
4. Construction
5. Size Designation
6. Load Capacity
7. Standardization
8. Products
8.1. Tires for Two-Wheel Vehicles
8.2. Passenger-Car Tires
8.3. Tires for Commercial Vehicles
9. Economic Aspects
10. Environmental Aspects

[Top of Page]

Tires belong probably to the most complex rubber products. There is hardly any technical rubber article which is so difficult to describe comprehensively in mathematical and physical terms and has such a wide-ranging profile of requirements including:

- Load carrying capacity
- Damping of road irregularities
- Adhesion on the road
- Transfer of longitudinal forces
- Transfer of lateral forces
- Immediate steering response
- Behavior as damped spring
- Dimensional stability
- Structural resistance
- Good mileage
- Low energy consumption
- Low noise generation

A tire functions mainly according to three physical principles [1], [2]:

1. *The spring behavior of the enclosed air:* The air enclosed in the tire acts as a spring and in a first approximation supports any kind of vehicle fitted with pneumatic tires.
2. *The rubber elasticity of the rubber components*: The action of tires is due to their rubber components that are dynamically deformed. In a vehicle, which can be modeled as a system of many components that are able to vibrate, tires act as dampened vibrators across a wide frequency spectrum.
3. *The rubber friction of the tread compound:* Due to the laws of rubber friction, tires are able to build up longitudinal and lateral forces in the contact areas with the road. These forces are necessary to move and to hold a vehicle on a road.

[Top of Page]

1. Tire and Vehicle [3], [4]

A large proportion of the properties of a pneumatic tire can be evaluated only if the tire is considered in combination with a vehicle. An overview on different vehicles is shown in Figure 1.

Figure 1. Applications of tires in different vehicles

The tire is an integrating component of the chassis and determines the quality of a vehicle to a large extent. Since the vehicle dynamics are differently designed from manufacturer to manufacturer, but also due to differences in riding comfort adjustment, the effect of one and the same tire in different types of vehicle – but above all in vehicles from different manufacturers – will be quite different. Furthermore, the evaluation of a tire on a vehicle is relevant only if the second acting partner of the tire, the road, is also taken into consideration.

[Top of Page]

2. Tire and Road [5-9]

Apart from the driver the most important reference element of the vehicle environment is the road surface. Some vehicles have to be used across a wide range of surfaces, for example military vehicles, agricultural or quarry vehicles, and mining industry vehicles. However, the majority of vehicles is intended to be used more or less exclusively on road surfaces specially designed for them. The road surface has a defined structure and is supported by a permanent foundation layer, that is, e.g., in Europe, made of asphalt macadam or concrete.

The kinematic design of a road depends on its intended use. In order to forecast and describe the vehicle movement on a road, the road design must be described physically.

For the description of the mutual interaction between road and tire it has proven to be advantageous to define the spectral distribution of the surface irregularities (Table 1.).

Table 1. Road spectral analysis

Characteristic		Wavelength	Influence on:
Slopes		50 m< λ	Pseudo-static
Undulations		1 m< λ<50 m	Dynamic (ride)
Roughness		10 mm< λ<1 m	Dynamic (NVH)
Texture	Macro	1 mm< λ<10 mm	Friction and noise
	Micro	10 µm< λ<1 mm	Friction
Material	Molecular	Friction	

Surface Irregularities. For wavelengths greater 50 m (ascents, hills) and vehicle speeds of approx. 20 m/s (70 km/h), the acting period of such irregularities is > 2.5 s; this is sufficiently slow for a vehicle to remain in the static balance of its suspension. For describing the tire behavior, these irregularities are not relevant.

Wavelengths of approx. 1–50 m, i.e., acting periods of 50 ms – 2.5 s, are designated as *undulations*. Undulations effect essentially a vertical dynamic response of the vehicle. This includes the excitation of the vehicle body with a resonance frequency of approx.1 Hz and the excitation of the resonance wheel frequency of approx. 10 Hz. These excitations are controlled or reduced by the spring/damper system (shock absorber). In coping with such vibrations, tires play only a minor role (influencing the vertical dynamics).

Wave lengths of 10 mm – 1 m, with acting periods of 0.5 – 50 ms, are called *roughness*. Roughnesses are essentially mastered by the tire deformation, and, in consequence, lead to a filtered dynamic response behavior of the vehicle (influencing the ride comfort).

Wavelengths under 10 mm influence the dynamics of a vehicle only to a minor extent. The respective acting period is < 0.5 ms. But within this wavelength range, the *road holding behavior* of the tire is mainly influenced (influencing the horizontal dynamics of the vehicle).

The subdivision of the roughness into macrotexture and microtexture (Fig. 2.) is the result of an analytic “dissection” of real roads in relation to their influence on tire friction.

Figure 2. Macro- and microtexture of road surfaces

Normally, the macrotexture is classified as “rough” or “smooth” whilst the microtexture is described as “harsh”. The macrotexture describes, e.g., the type of gravel used in an asphalt surface (1–10 mm) and thus the extent to which it protrudes from the matrix surface or has been rolled into the same.

The microtexture on the other hand describes the surface properties of the gravel elements. The influence of both characteristics can be seen on dry but even more pronounced on wet road surfaces. Here, the macrotexture assists in the actual water displacement in the contact area of the tire and road and thus supports the effect of the tire tread pattern, whilst the harsh microtexture – similar to the lamellas of a tire tread pattern – provides for local ground pressure and thus ensures the removal of the water film produced.

Under wet road surface conditions, surface porosity has an additional influence on water drainage (aquaplaning). In the case of dense nondivisible surfaces (e.g. concrete), this water displacement task must be performed by the tire tread pattern alone. By the way, tires with tread patterns are not required if surfaces are dry, smooth and consistent (frictional connection only!). If the “roughness” is of molecular magnitude, then the road surface material influences strongly the actual frictional connection of a tire (“adhesion”–related).

As far as the tire properties on a vehicle are concerned, above all with regard to handling, the road characteristics must always be taken into consideration. Thus, tire properties are tire/road surface properties.

[Top of Page]

3. Tire Characteristics [10-12]

As mentioned previously, the motion of a vehicle is practically determined totally by the forces which the road surface exerts on the tires. Thus, the tire characteristics (materials, structure, geometry) have a considerable influence on the handling of a vehicle. Within the tires, the forces must be generated, that “carry” the vehicle load (*load capacity*) and “move” the same (acceleration, braking, cornering).

However, the tire equipment must also serve as an intermediate medium to disengage the vehicle from road surface irregularities (*ride comfort*) and to provide a maximum number of kilometers travelling distance (*mileage*), and all this with maximum reliability for its entire service life (structural integrity).

Handling (Horizontal Dynamics). The contact areas of the four tires (for two- track vehicles, in the case of two-wheel vehicles there are only two tires), that is, the interacting tire/road areas, are the locations where the necessary forces for the required kinematic behavior of a vehicle are generated (Figs. 3. and 4.). The pneumatic tire made from rubber and equipped with a reinforcing material (carcass) has been the ideal technical product for this purpose without any alternative right from the start, i.e. for more than a hundred years now. The dominance of this construction principle is essentially the result of the rubber properties of the tire construction elements. Rubber elasticity and rubber friction render the tire suitable for load bearing and moving the same under very different ambient conditions (Fig. 5.). For a given tire/road surface pair, the lateral force – built up in the contact area by a specific vertical load and a specific internal tire pressure – mainly is a function of the slip angle (angle position of the tire relative to the direction of travel) and the tire camber (Fig. 4.). It is furthermore a rule that the longitudinal forces (acceleration forces, braking forces) can only be generated by slip (relative movement of the contact area to the road surface).

Figure 3. Tire forces

Figure 4. Force exerted by the ground by side slip and camber

Figure 5. Tire friction in longitudinal direction

Due to the many dependencies it is practically impossible to predict the magnitude of the resulting lateral force on a tire under real conditions of handling and even less so the resulting lateral movement of a vehicle with four tires: This is due to the fact that the tire characteristics vary strongly from manufacturer to manufacturer, the vehicle concepts can be very different; and the road surfaces can vary greatly, which results in a strong variation of grip and time behavior, running performance (caused by the frictional wear behavior of the tire), etc.

Ride Comfort Behavior. To describe its behavior on the vehicle, a pneumatic tire can be represented as a spring-type action-damper combination (Fig. 6.). Its speed- and frequency-dependent spring-type action or damper behavior is determined by the air pressure inside the tire, geometry factors of the tire-rim combination and by the material components of the tire itself (elastic properties of the reinforcement carriers, rubber elastic properties of the rubber matrix materials). Depending on their actual frequency, the vibrations induced by the road surface during the rolling process (or by tire irregularities, tire nonuniformity) are transmitted to the vehicle via the axles; in this process, the vibrations are dampened by the tire to a greater or lesser degree. Therefore, the ride comfort of a vehicle is determined largely by the tires, acoustically (acoustic comfort) as well as on a tactile basis (plastic comfort).

Figure 6. The tire as a part of the vibrating system vehicle

[Top of Page]

4. Construction [13]

Tire Reinforcements. The essential construction element of a pneumatic tire is the *carcass*, a rubber compound matrix, reinforced by one or several layers of textile or metal cord fabric. The carcass “contacts” the wheel rim on both sides (beads). The tire beads are used to fix the cord reinforcement, wrapping it around the bead cable (carcass wrapping), and on its external surface to “attach” the tire to the rim. The metal bead cables are rubberized and shaped such that they compress the carcass firmly onto the rim seats (incline from 5–15°) under the internal air pressure of the tire.

For passenger car tires, depending on load capability or speed category, the internal air pressure is 1.5–3.5 bar; in the case of commercial vehicle tires (trucks) 7.0–9.0 bar (higher loads).

Depending on the actual use of the tire, the reinforcing materials (*tire cords*) are normally made of rayon, nylon, polyester, aramid or “brassed” steel. The tire cords have a higher elastic modulus than the rubber matrix. Also, their creep behavior is significantly lower. In this way, in the case of pneumatic tires, they take up the forces built up by the internal tire pressure and kinematic vehicle movements, and transmit them to the road. Thus, very significant tensions are applied in the tire cord. The tensions influence all tire properties such as handling, comfort, wear etc.

In the case of a *radial tire* the carcass cords (one layer) run from bead to bead, 90° to the running direction of the tire (see Fig. 7.). In *diagonal* (*bias*) *tires*, the tension direction runs at approx. 35–40° to the running direction (diagonally), with two or more cord layers with a respective mirror-symmetric angle position of the cords being necessary here (Fig. 8.). The rubberization of the cords is relatively soft (low filled compounds) in order to ensure a good fatigue behavior at dynamic tire loads.

Figure 7. Construction of a radial tire

Figure 8. Construction of a diagonal tire

In a radial tire, the carcass is fixed in its position — and thus its cross-section contour — by a *belt*, mostly made up of steel cord “bandages” of a defined width crossed at an angle of 20–30°. This principle makes it theoretically possible to produce any cross-sectional tire contour (low-section tires); this is one of the essential benefits of this construction as compared to the diagonal principle.

Tire Compounds. In a radial tire, the belt is circumferentially surrounded by the *tread*. The tread is the contact medium to the road surface and is thus used to build up the driving forces and also for the transmission of forces “into the tire”. The tread is equipped with a *tread profile* featuring longitudinal and transverse grooves as well as lamellas with a depth of approx. 8 mm in the case of tires for passenger cars, and 12–20 mm (depending on the area of use) in the case of commercial vehicles. The profile is essentially used for the drainage of water on a compact road surface or for the generation of acceleration and deceleration of the vehicle on loose road foundations by means of form fit (traction). The tread compound must be relatively hard (highly filled) in order to ensure a good running performance; otherwise the grip to the road surface must be assured by means of the composition and deformability of the profile elements (block stiffness). Typical passenger car tread compounds feature blends of SBR and BR whilst commercial vehicle tread compounds – depending on their area of use – consist of 100% NR or blends of NR with SBR and/or BR.

Modern passenger car and commercial vehicle tires are *tubeless*, i.e., as their innermost rubber layer the tires contain a membrane (liner) which is highly non-permeable for air. As a result of the combination of tubeless tires with air-tight wheel rims (tubeless rims) the tubes used as standard formerly have become obsolete; this increases safety, is an advantage for mounting capability and reduces the weight of the tire system.

In total, a tire is composed of up to about ten different compounds which in themselves are again built up from different rubber blends (natural rubber, SBR, BR), fillers (carbon black, silica), softeners (oils, resins), antiaging agents and vulcanization systems (sulfur, accelerators), that are designed for the locally required mechanical and thermal properties of the tire components. A car tire contains 50% rubber (natural and synthetic), 26% carbon black and other fillers, 14% textile and steel cord, 5% bead wire and 5% vulcanization accelerating and antiaging system chemical (Fig. 9.). The required properties of tire compounds are listed in Table 2.

Figure 9. Tire materials

Table 2. Required properties of fire compounds

Tire Component	Requirements	Rubber used within	
		Passenger Car	Truck
Tread	low wear	SBR/BR/(75/25 to 55/45)	NR
	high friction		
	low hysteresis	NR/SBR/BR(25/35/40)	NR/SBR/BR (50/30/20)
	low tearing		
	Ozone resistance		
Casing	high elasticity	NR/BR (50/50)	NR/BR
	good adhesion to textile cord		
	low hysteresis		
Belt	good flow	NR	NR
	good adhesion to textile cord		
	low hysteresis		
	fatigue/tear resistance		

Apex	high modules good adhesion	NR	NR
Linear	bending strength low permeability curing properties	Halobutyl NR/SBR (60/40) NR/Halobutyl	Halobutyl

The actual tire geometry and the selection of the materials for the various components (compounds, reinforcements) of a tire must be carefully balanced by the tire development engineer. Even if an individual tire property can be optimized, this is in most cases connected with significant detrimental effects on other tire properties (interdependent variables).

[Top of Page]

5. Size Designation

A tire size refers to two base dimensions of a wheel rim, the rim diameter and the associated rim width. On the rim, the tire is “built” up, with the dimensional measures tire width and cross-sectional height. The external tire diameter results from the rim diameter and cross-sectional height (Fig. 10.).

Figure 10. Tire cross-section

Since the 1960s there has been a trend leading – on a wide scale – to tires with steadily decreasing cross-sectional heights. This is because on the one hand lower cross-sectional heights provide significant advantages especially with respect to the handling of any type of vehicle, and because it was possible on the other hand to compensate their poorer comfort on the vehicle. Modern motorcycle and passenger vehicle tires range from a cross-sectional ratio of 80 over 70, 65, 60, 55, 50, 45, 40, 35 to 30. Even for commercial vehicle tires cross-sectional ratios of 100, 85, 80, 75, 70, 65, 60, 50 and even 45 for super single tires are found today (Fig. 11.).

Figure 11. Development of the tire cross-sectional ratio

[Top of Page]

6. Load Capacity

In a first approximation, the tire load capability is determined by the air volume of the tire and the internal tire pressure. When loaded, the tire experiences a vertical deflection. During the rolling process, this leads to a cyclic deformation of the tire in the running surface, belt and side wall areas; and due to the rubber elastic, hysteresis-type properties of the rubber components involved, this also leads to energy losses (rolling resistance, heat build up).The permitted tire deflection and thus the permitted load depends on the load-time duration of the tire application (e.g. aircraft tires: short term maximum loads with high deflection; commercial vehicle tires: long-term high load with low deflection). Non-permitted high loads, excessive speed, insufficient tire air pressure and unfavorable chassis geometries (e.g. a high camber) lead to nonpermitted high deflections and thus a major heat build up in the rubber materials. As a consequence this leads to tire failures (bubble formation, chunking of block elements, belt separations, and finally tire bursts).

[Top of Page]

7. Standardization [14]

The purpose of tire standardization is the worldwide interchangeability of products from different manufacturers. Standardization encompasses the tire designation and the tire dimensions. In addition, it comprises the correlation between tire load carrying capability and tire pressure as well as the influence of vehicle parameters such as maximum speed and wheel camber. Also, the assignment of the recommended and permitted rims is controlled by the standards.

The ISO, in Europe ETRTO (European Tire and Rim Technical Association), in the USA T&RA (Tire and Rim Association), and in Japan JATMA (Japan Automobile Tire Manufacturers Association) are responsible for standardization. At a national level, the following are also active: e.g. AFNOR in France, BSI in the UK, in Germany DIN as well as WdK (Wirtschaftsverband der Deutschen Kautschukindustrie).

In addition, in some countries there are tire-approval regulations for tires as vehicle components. These serve to provide road traffic safety and differ from country to country. International safety legislation and safety codes are listed in Table 3.

Table 3. Safety legislation and safety codes

8. Products

8.1. Tires for Two-Wheel Vehicles

For their own stabilization – which is based on the gyroscopic principle – two-wheel vehicles with tilt instability always require a lateral force component to assure lateral guidance. The lateral forces, that the tire has to build up, are mainly compensated by the inclined position of the vehicle, i. e., by its camber.

The significantly lower running performance of motorcycle tires as compared to passenger car tires is caused by the lower

contact area and, in the case of motorcycles with powerful engines by the greater forces to be transmitted to the road (greater slip).

Up to the early 1980s only diagonal tires were used for two-wheel vehicles. With the increase in vehicle engine power and speed — above all in the case of motorcycles — the diagonal construction principle reached the limits of its performance capability (tire growth, insufficient contour reliability, with the consequences high wear, insufficient grip in curves, and poor suitability for high speed). Radialization provided the technical solution to the problem (twice bent shell geometry).

Depending on the vehicle (type, construction), a range of different tire constructions are today on the market (see Figs. 13. and 14.).

Figure 13. Segmentation of motorcycle tires

Figure 14. Construction of motorcycle tires

8.2. Passenger-Car Tires

In the highly industrialized countries with good road systems and high vehicle speeds, passenger-car tires are built practically exclusively according to the *radial principle*. The tires are classified according to their use (summer tires, winter tires, see Fig. 15.).

Figure 15. Segmentation of passenger-car tires

The typical requirements for European *summer tires* are:

- Best performance on good, solid road surfaces
- No loss of performance even at temperatures >50 °C
- High speed capability
- Maximum dry adherence
- Maximum wet adherence
- Aquaplaning resistance
- High steering precision and stability
- High comfort
- Minimum noise generation on all road surfaces
- High mileage
- No loss of air

The following requirements must be met by a Central European *winter tire*:

- Use from –25 to +7 °C
- Use on dry and wet surfaces, temporarily covered with snow, ice and mud
- High dry adherence
- High wet adherence
- Traction on ice and snow
- Traction on mud
- Aquaplaning resistance
- Steering precision and stability
- Good comfort
- Low noise generation
- High mileage
- High speed capability (“H”)

As winter conditions are very different in the mountains or in arctic countries, the requirements for extreme ice and snow tires differ quite strongly from the Central European type:

- Use from –40 to +7 °C
- Use on irregular surfaces, covered for months with ice and snow
- Traction on ice (also with studs!)
- Traction on cold, loose but also hardened snow
- Good mud performance

In the USA, all-season tires have become dominant. These tires constitute a compromise between summer tires and

Central European winter tires. A comparison between all-season and European winter tires is given in Table 4 and Fig 16.

Table 4. Requirements of all seasons tires in comparsion with European summer tires

Criteria	Demands in reference to base
Dry handling, lateral dynamics	losses acceptable
Straight ahead, longitudinal grooves	at least equal
Wet handling performance	losses acceptable
Aquaplaning	equal
Comfort	noticeable better
Noise	noticeable better
Mileage	significant better
Irregular Wear	low
Winter Performance	minimum mobility
Vibrations and Flat Spot	equal
Weight, Rolling Resistance	significant better
Brand acceptance	preprequisite

Figure 16. Performance of all season tires vs. European summer tires

Depending on the vehicle speed, tires are offered with different speed symbols (S ≤ 180 km/h, T ≤ 190 km/h, H ≤ 210 km/h, V ≤ 240 km/h, W ≤ 270 km/h, Y ≤ 300 km/h, Z ≥ 300 km/h), see Fig. 17.). Depending on the manufacturer, tires feature different tread patterns (technical properties, optical appearance).

Figure 17. Different Pirelli car tires

In the case of passenger cars, one aim of the vehicle industry is to eliminate the spare wheel to this end, so-called *run -flat systems* have been developed. In the event of a loss of air because of a tire puncture, these systems provide for the “onward movement” of the vehicle (> 200 km) without having to change the tire until a service point is reached (Fig. 18.).

Figure 18. Self supporting tires

Figure 19. Run flat system

8.3. Tires for Commercial Vehicles

In principle, the same requirements as for passenger cars apply to commercial vehicles; however, economic efficiency is of prime importance here. Apart from all security arguments the predominant economic factors are:

- Good mileage
- Regular wear (between tire “center” and “shoulder”)
- Low rolling resistance (for low fuel consumption!)

- High reliability
- Low tire weight
- Regroovability
- Retreadability of the casing (more than three times)
- Low cost of the tire

In addition, depending on the kind of use, the following may be important:

- Traction
- Comfort (tactile)
- Easy mounting of snow chains

In comparison with passenger-car tires, tires for commercial vehicles have to cover a wider range of total vehicle weight, vehicle performance, and areas of use. This leads to widely differing tire requirements. A classification of commercial tires is given in Figure 20.

Figure 20. Classification of commercial tires

In Europe mainly *radial tires* are used for commercial vehicles. In countries with lower vehicle speeds and poorer road conditions, however, *diagonal tires* are predominantly in use. Also, *tubeless tires* are standard in Europe. Different types of Pirelli truck tires are presented in Figure 21.

Figure 21. Pirelli truck tires

[Top of Page]

9. Economic Aspects [14]

In 2001 the world tire production was 1141 × 10^6 units, 822 × 10^6 of which were tires for passenger cars, 319 × 10^6 units were produced for commercial vehicles. The world tire production for passenger cars and commercial vehicles by geographical area is shown in Table 5. Production broken down by leading manufacturing countries is listed in Table 6

10. Environmental Aspects [15]

Due to tire wear on the road surfaces caused by rubber friction, tire wear material in the form of minute rubber particles (30–70 µm) is generated. On average, approximately 60 000 t rubber wear material is produced in this way per year in Germany (for example). The wear material contains mainly degraded rubber and carbon black, and in addition approximately 1% zinc in the form of its oxide, the oxide being contaminated by approximately 1 % lead and cadmium. Tire wear material does not represent any health hazard as it is naturally degraded chemically as well as bacteriologically.

1. Introduction

Titanium, Ti, atomic number 22, relative atomic mass 47.88, is a member of group 4 of the periodic table. It has two 4 *s* and two 3 *d* valence electrons and is a transition element. The electronic configuration is $1s^2\,2s^2p^6\,3s^2p^6d^{\,2}\,4s^2$. Natural titanium is a mixture of five stable isotopes [7]:

Mass number:	46	47	48	49	50
Abundance, %:	7.95	7.75	73.43	5.51	5.34

The following unstable isotopes also exist:

Mass number:	43	44	45	51
Half-life:	0.58 ± 0.004 s [8]	1000 a	3.08 ± 0.06 h [9], 21 d [10]	6 min [11], 72 ± 2 d [12]

History. In 1791, GREGOR isolated a metal oxide from the black, magnetic iron-containing sand found at Manaccan in Cornwall, and conjectured that it contained a hitherto unknown metal, which he named manaccanite. In 1795, KLAPROTH investigated the red schorl rock from Boinik in Hungary, and he also decided that this mineral must contain an as yet unknown metal, which he named titanium after the Titans, the sons of the primeval Earth Mother. After detecting the new metal, also in oxidic form, in other minerals such as titanite and ilmenite, KLAPROTH showed that it was identical with the metal in manaccanite.

Although the fundamental reactions of modern titanium production (digestion with sulfuric acid, hydrolysis of the resulting liquor, and re-

duction in acidic solution) were already known before 1800, the first preparation of pure titanium oxide was carried out only in 1908, while full-scale production began in 1916 in Norway.

In 1910, HUNTER prepared 98 – 99 % pure titanium metal by reduction with sodium. The strong affinity of titanium for oxygen, nitrogen, and carbon made preparation of the pure, ductile metal difficult, and this was first achieved by VAN ARKEL in 1922 by reducing potassium hexafluorotitanate with sodium in an inert atmosphere. The foundations for large-scale industrial production were laid by KROLL's discovery of the reduction of titanium tetrachloride by magnesium. WARTMAN of the Bureau of Mines then developed a method of treating the titanium sponge so obtained and melting it in an electric arc furnace.

2. Physical Properties

Pure titanium is a silvery white, ductile metal, *mp* 1668 ± 50 °C [13, 14], *bp* 3500 °C [15]. The atomic radius is 0.145 nm for coordination number six in the crystal lattice [16].

α-Ti has hexagonal structure of the Mg type, almost close-packed and somewhat compressed along the *c*-axis. The lattice constants of α-Ti at room temperature are $c = 0.4679$ nm, $a = 0.2951$ nm, $c/a = 1.585$ for twice-refined iodide titanium [17].

At 882.5 °C [18], titanium transforms into the body-centered cubic β-phase, the heat of transformation being 3.685 kJ/mol [19]. Extrapolation of the lattice constants of titanium alloys whose β-phase can be quenched to room temperature, gives a lattice constant $a = 0.3269$ nm at room temperature [20] and 0.328 nm above 620 °C. Increasing contents of oxygen, nitrogen, and carbon, which are incorporated interstitially, slightly elongate the *a*-axis of α-Ti and considerably elongate its *c*-axis. These effects are most marked with carbon, and are very slight with hydrogen. The effect on the lattice constants of titanium of elements that form substitution mixed crystals is variable.

Some important physical data of titanium are as follows:

Density at 25 °C	4.5 g/cm^3 (high purity)
	4.51 g/cm^3 (commercial purity)
at 870 °C (α-Ti)	4.35 g/cm^3
at 900 °C (β-Ti)	4.33 g/cm^3
Coefficient of linear expansion at 25 °C	8.5×10^{-6} K^{-1}
Mean coefficient of linear expansion, 20 – 700 °C	$(9.0 - 10.1) \times 10^{-6}$ K^{-1}
Latent heat of fusion	20.9 kJ mol^{-1}
Latent heat of sublimation	464.7 kJ mol^{-1}
Latent heat of vaporization	397.8 kJ mol^{-1}
Specific heat capacity	
at 25 °C	0.523 J g^{-1} K^{-1}
at 200 °C	0.569 J g^{-1} K^{-1}
at 400 °C	0.628 J g^{-1} K^{-1}
Thermal conductivity at 20 – 25 °C	0.221 W cm^{-1} K^{-1} (high purity)
	0.226 – 0.201 W cm^{-1} K^{-1} (commercial purity)
Surface tension at 1600 °C	1.7 N/m
Diffusion coefficient (self diffusion)	
at 750 °C (α-Ti)	4×10^{-13} cm^2/s
(β-Ti)	2.4×10^{-9} cm^2/s
Modulus of elasticity at 25 °C	100 – 110 GPa
Temperature coefficient	− 0.687 GPa/K
Modulus of rigidity at 25 °C	411.8 – 431.5 GPa
Temperature coefficient	0.265 GPa/K
Bulk modulus at 25 °C	122.6 GPa
Transverse contraction number at 25 °C	0.30
Electrical resistivity	
at 25 °C	42 μΩ · cm
at 600 °C	140 – 150 μΩ · cm
Superconductivity (iodide titanium), transition temperature	0.40 ± 0.04 K
Magnetic susceptibility of α-Ti at 25 °C	3.2×10^{-6} cm^3/g
Temperature coefficient for − 200 to 800 °C	0.0012×10^{-6} cm^3 g^{-1} K^{-1}
Magnetic permeability at 25 °C	1.00005

Further details can be found in [13–15, 21–37]. Many properties of titanium at a given temperature show variations that depend on the composition and condition of the metal (purity, alloying elements, thermal and mechanical pretreatment).

Variation in properties such as electrical and thermal conductivity and plastic behavior are caused by lattice defects. Cold working increases hardness and strength by producing dislocations, and reduces modulus of elasticity and electrical conductivity, e.g., by producing holes in the lattice. Annealing in the recovery range (300 – 500 °C) and in the recrystallization range (500 – 800 °C) restores the original values. The moduli of elasticity and shear elasticity also depend on heat treatment. The presence of foreign elements, even at low concentrations, often has

a marked effect. In general, electrical resistivity, hardness, and strength increase with decreasing purity.

3. Mechanical Properties

High-purity titanium (iodide and electrolytic titanium) still contains traces of other elements due to the high affinity of the metal for atmospheric gases. Above room temperature, the strength decreases, by 50 % at 200 °C, whereas the fracture strain remains virtually unchanged. Increasing the grain size decreases tensile strength and yield strength but increases elongation and reduction in area at fracture. Compositions and mechanical properties of high-purity titanium grades are listed in Table 1.

Titanium of Commercial Purity. As oxygen, nitrogen, and hydrogen contents increase, strength increases and toughness decreases. Whereas oxygen is the only element deliberately added to give increased strength, the others, together with iron and carbon, are impurities introduced during production.

The chemical compositions and strength properties of commercial grades of titanium in the recrystallized-annealed state are listed in Table 2. The Grade 1 material is the softest grade of titanium, and has excellent cold working properties. It is used for deep drawing, cladding of steel reactors, as a coating applied by explosive cladding, for components that must have good corrosion resistance but need not have high strength, and in electrical technology. Titanium Grade 2 is the most widely used commercially pure titanium. It has good cold working properties, and may also be used for load-bearing components at temperatures up to ca. 250 °C. Titanium Grade 3 is used almost exclusively for pressure vessels. This material has adequate cold-working properties and can be used at lower wall thicknesses than softer grades of titanium. Titanium Grade 4 has the highest strength and is used for the manufacture of fittings and in aircraft construction. Complex components made of this grade of titanium have to be formed at ca. 300 °C.

As shown in Figure 1, the high-temperature tensile strength of all industrial grades of titanium decreases rapidly with increasing temperature. As titanium creeps under prolonged stress even at room temperature, the characteristic high-temperature strength values used in calculations based on 100 000 h periods, as required for chemical pressure vessels, are considerably lower than those for short periods [40]. The use of titanium Grade 1 for pressure vessels is not recommended.

Figure 1. High-temperature tensile strength and fracture strain of titanium and values used for titanium pressure vessel calculations (10^5 h)
Titanium grade numbers are explained in Table 2

In addition to the fundamental strength properties determined by destructive testing and the creep strength values determined by long-term static load tests, fatigue strength (resistance to oscillatory stress) is also important. In the case of titanium, it is between 50 and 75 % of the ultimate tensile strength.

Cold working (80 – 90 % deformation) doubles the tensile strength of titanium, and both the elongation and reduction in area at fracture decrease by ca. 50 %.

4. Corrosion Behavior (→ Construction Materials in Chemical Industry, Chap. 5.9.)

The standard electrode potential of the reaction $Ti \rightleftharpoons Ti^{2+} + 2e$ is -1.75 V. The corrosion resistance of titanium metal is due to the formation of a thin, dense, stable, adherent surface film of oxide, which immediately reforms after mechanical damage if oxygen is present in the

∗ DIN 17 850, Nov. 1990 and DIN 17 860, Nov. 1990.

surrounding medium. Titanium is less resistant to corrosion in strongly reducing media.

The corrosion-resistant oxide layer is destroyed in completely water-free environments such as dry chlorine, dry oxygen, and red-fuming nitric acid, and in reducing corrosive media. In neutral aqueous solutions, especially in the presence of chloride ions, localized penetration of the passive layer can lead to pitting and crevice corrosion.

Passivation. In a corrosive medium, the electrode potential of a titanium surface decreases with time [41]. The passivation potential usually lies between -0.2 and -0.5 V. With increasing concentration and temperature, the passivation current density increases in the passive range, while the passivation potential remains constant [42]. The corrosion loss in the passive range therefore increases [43]. Small additions of oxidizing metal ions such as Cu^{2+}, Fe^{3+}, Cr^{4+}, Au^{3+}, and Pt^{4+} cause passivation of titanium in reducing media. With increasing temperature and acid concentration, the concentration of inhibitor necessary to give passivation increases. Anodic treatment strengthens the coatings and can delay their degradation under reducing conditions.

Additions. The corrosion behavior of titanium-based materials can often be improved by the addition of at least 0.15 % palladium to the alloy, without affecting its strength properties [44, 45].

Likewise, small additions (< 1 %) of other noble metals improve the corrosion behavior of titanium [46]. Improvement of corrosion resistance as well as strength properties is achieved by addition of, e.g., 0.8 % nickel with 0.3 % molybdenum [47].

Crevice Corrosion, Stress Corrosion Cracking, and Pitting. Titanium is not very susceptible to crevice corrosion (→ Corrosion, Chap. 3.2.2.) except at elevated temperatures in the presence of high concentrations of halide and sulfate ions or in moist chlorine gas. Additions of palladium to the alloy have a beneficial effect. Titanium is very resistant to pitting in the presence of chlorides, except in high concentrations of chlorides of calcium, aluminum, or zinc at elevated temperatures [48]. Titanium is not susceptible to stress corrosion cracking, except by red-fuming nitric acid containing < 1.5 % water, by uranyl sulfate, or by anhydrous methanol.

Reaction with Hydrogen, Oxygen, Nitrogen, and Air. The presence of hydrogen (produced in a chemical process or as a corrosion product) or of hydrogen-containing compounds leads to local hydrogen pickup by titanium, with consequent embrittlement and impairment of corrosion resistance. The rate of hydrogen pickup depends on temperature, time, and the

condition of the metal surface [49]. Oxide coatings reduce or prevent hydrogen pickup [50].

The oxide film that forms on the surface of activated titanium metal at room temperature reaches a thickness of 1.7 nm in 2 h, 3.5 nm in 40 d, and 25 nm in 4 years [51]. The color of the oxide film varies with its thickness and temperature of formation, and also with the alloy content of the parent metal. As the temperature increases from 200 °C to ca. 500 °C, the film thickness increases, and its color changes from golden yellow to brown, dark blue, violet, and light blue, showing iridescent effects, while at higher temperatures a gray haze forms followed by a silvery-white and then a dirty gray scale layer, after which a yellowish white to brown scale layer of variable thickness appears, depending on the alloy composition [52]. With increasing heating time and temperature, the depth of penetration of oxygen, and hence the hardness, increases [53].

Table 3. Corrosion behavior of commercially pure titanium

Resistant	Limited resistance	Nonresistant
Nitric acid	Sulfuric acid	Fluorine
Chromic acid	Hydrochloric acid	Dry chlorine
Sulfurous acid	Phosphoric acid	gas
Alkali lyes	Oxalic acid	Red-fuming
Ammonia	Formic acid	nitric acid
Aqueous chlorides		
Brine		
Seawater		
Wet chlorine gas		
Acetic acid		
Maleic acid		
Acetaldehyde		
Carbamate		
Dimethylhydrazine		
Liquid hydrogen		

Up to ca. 500 °C, the weight increase of titanium due to oxidation is small. Higher temperatures lead to a rapid weight increase associated with dissolution of oxygen in the metal.

In a nitrogen atmosphere, a titanium nitride layer with metallic character is formed. Above 700 °C, the titanium nitride increasingly reacts with oxygen to form titanium oxide. Titanium reacts with nitrogen considerably more slowly than with oxygen, so that the reaction with nitrogen makes little contribution to scale formation in air. In the presence of water vapor, hydrogen is also taken up.

Behavior in Salts, Bases, Acids, and Molten Materials. The corrosion behavior of commercially pure titanium is summarized in Table 3. Oxidizing conditions and the presence of oxidizing agents under reducing conditions improve corrosion resistance, whereas strongly reducing conditions or increases in concentration and temperature impair it [52].

Titanium is stable in molten alkali metals up to 600 °C, in magnesium up to 650 °C, in gallium, tin, lead, and lead – bismuth – tin alloys up to 300 °C, and in mercury up to 150 °C [54]. Titanium is corroded by molten mixtures of chlorides and fluorides.

5. Occurrence

Titanium is relatively widely distributed and abundant. With an estimated average concentration in the earth's crust of 0.6 %, it is ninth in order of abundance after oxygen, silicon, aluminum, iron, magnesium, calcium, sodium, and potassium. Its concentration is ca. 1/20 that of aluminum, and 1/10 that of iron. It is 5 – 10 times as abundant as chlorine, sulfur, or phosphorus, and more abundant than the rest of the metals put together. Thus, for example it is 60 times as abundant as copper or nickel and 300 times as abundant as molybdenum.

As the ionic radius of titanium is similar to that of some of the most common elements (Al^{3+}, Fe^{3+}, Mg^{2+}), most minerals, rocks, and soils contain small amounts of titanium, although true titanium minerals, containing > 1 wt % titanium, of which there are at least 87, are found in only a few locations.

Primary titanium occurs in igneous rocks, where it forms the acidic component of basic magmas and the basic component of acidic magmas. In the first case, titanates are present, the most important of which are ilmenite ($FeTiO_3$) and perovskite ($CaTiO_3$). In the second case, oxidic compounds of titanium are formed. Intermediate forms also exist, e.g., in silicates, in which titanium is present mainly as a basic element (e.g., in zircon minerals and aluminosilicates), but also as a replacement for silicon. These transitional forms include titanite (sphene), $CaTi(SiO_4)O$, a common component of magmatic rocks. All these forms also occur

in metamorphic titanium-containing rocks. The two TiO_2 modifications anatase and brookite occur exclusively in metamorphic deposits.

Secondary deposits of titanium include the widely distributed ilmenite placer deposits and ilmenite sands, which mostly occur in coastal regions, and the TiO_2 deposits in clays. Ilmenite is the main starting material for titanium dioxide pigments.

The most important titanium minerals are anatase (TiO_2); ilmenite ($FeTiO_3$), which contains up to 53 % TiO_2, and its low-iron weathering product leucoxene; perovskite ($CaTiO_3$); rutile (TiO_2); and sphene [$CaTi(SiO_4)O$]. Of these, only ilmenite, leucoxene, and rutile are of economic importance due to the ease with which they can be processed. The anatase deposits in Brazil and the perovskite deposits of Colorado (United States) may achieve economic importance in the future.

The most useful mineral for the extraction of titanium and titanium compounds is rutile (TiO_2). Although it is rarer than ilmenite, its TiO_2 content is higher. Naturally occurring enriched rutile is brown to black, and contains 90–97 % TiO_2 together with impurities including up to 10 % silica, iron oxides, vanadium, niobium, and tantalum, and traces of tin, chromium, and molybdenum compounds.

Primary rutile deposits occur at Kragero in south east Norway (albite with 25 % rutile) and in Virginia (United States). However, more important are the secondary placer deposits, e.g., in Brazil, Cameroon, and Arkansas (United States), and the beach sands, of which the most important are on the east coasts of Australia and Florida (United States) and in northern Transvaal (South Africa). All rutile and two-thirds of ilmenite are extracted from placer deposits and sands, the rest of the ilmenite being obtained from titanomagnetites and titanohematites.

Rutile-bearing beach and dune deposits can be mined if TiO_2 contents exceed 0.3 %. The TiO_2 content of the ilmenite sands depends on the degree of weathering. In the South African deposits it is 10–48 %, in Australian sands 54 %, and in ilmenite from Kerala (India) and the east coast of Sri Lanka up to 80 %. The ilmenite-bearing titanomagnetites and titanohematites contain 35 % TiO_2 in Canada, ca. 20 % in the United States, 18 % in Norway, and 13 % in Finland [55].

Titanium occurs in many stars. It is less abundant in meteorites than in the earth's crust, and is mainly associated with the silicate phase [56].

Reserves. Proven world reserves of rutile and ilmenite, calculated as TiO_2, content have been estimated at 423×10^6 t to 600×10^6 t. The largest reserves of ilmenite are in South Africa, India, the United States, Canada, Norway, Australia, Ukraine, Russia, and Kazakhstan, and of rutile in Brazil [57]. The existence of other reserves, e.g., in Bangladesh, Chile, Italy, Mexico, and New Zealand, makes it likely that the actual mineable world reserves considerably exceed the accepted figures.

6. Production of Titanium Tetrachloride

Titanium metal is produced exclusively by reduction of titanium tetrachloride, which is manufactured from natural rutile or from the so-called synthetic rutile obtained from ilmenite or from the TiO_2-rich slag produced by metallurgical treatment of ilmenite (ore preparation, production of TiO_2-rich slags, and production of synthetic rutile are described in → Pigments, Inorganic, Chap. 2.1.2.2.).

The TiO_2 produced for the pigment industry by treatment of ilmenite with sulfuric acid (→ Pigments, Inorganic, Chap. 2.1.3.) is unsuitable as a starting material for production of the metal because of the impurities present. Also, titanium white (TiO_2) is increasingly produced from $TiCl_4$ (→ Pigments, Inorganic, Chap. 2.1.3.3., → Pigments, Inorganic, Chap. 2.1.3.2.). At the present time, approximately one-third of TiO_2 world production (2.1×10^6 t/a) is produced by the chloride process. Over 95 % of the total quantity of titanium minerals extracted worldwide is used to produce TiO_2 pigment, and only ca. 4 % for titanium metal.

In spite of the wide distribution of titanium minerals, the mining of rutile-containing ores is mainly concentrated on Australia, from which 90 % of world production comes. Other important producing countries are Sierra Leone

and South Africa. The most important ilmenite-producing countries are Australia (one-third of total world production) and Norway, the United States, and the Ukraine, while the leading producers of titanium slag from ilmenite are Canada and South Africa.

Chlorination of titanium dioxide is now carried out almost exclusively by the fluidized-bed process.

In the discontinuous fixed-bed process, which is now hardly used, rutile concentrate (> 96 %) is mixed with 20 – 25 % petroleum coke and a binder (wood tar, asphalt, etc.), sometimes with added catalysts (e.g., MnO_2), and briquetted [58]. The briquettes are stacked in the lower part of a brick-lined chlorination tower over a layer of carbon which acts as an electrode, and are reacted with chlorine at 500 – 850 °C. The chlorine gas is heated to ca. 1000 °C by the resistance-heated carbon bed and then reacts exothermically with the rutile and carbon in the briquettes.

The process can also be carried out in two stages, in the first of which rutile is reduced by carbon at 1200-1400 °C to give titanium carbide and titanium monoxide. The latter reacts with chlorine more readily than rutile.

Since ca. 1950, chlorination has been carried out almost exclusively by the fluidized-bed process (→ Pigments, Inorganic, Chap. 2.1.3.2.) because of its higher reaction rate and improved heat transfer, and also because of the shortage of briquetting facilities. Also, higher temperatures (ca. 1000 °C) can be achieved. After the reaction has started at ca. 600 °C no further external heat supply is necessary. Apart from the benefit of continuous operation, fluidized-bed chlorination has the further advantage of being less sensitive to impurities in the rutile or the carbon. The conversion of chlorine is 95 – 100 %, of rutile titanium 90 – 95 %, and of carbon 95 %.

Ilmenite is now less often used as starting material, because of excessive chlorine consumption due to formation of iron(III) chloride for which there is little demand and from which chlorine can only be recovered at high cost. Furthermore, in spite of its higher boiling point, $FeCl_3$ is entrained by the $TiCl_4$ vapor and is deposited in the coolers as a powder, its solubility in liquid $TiCl_4$ being only 0.03 % [59].

In contrast to the ilmenite-treatment process, the treatment of TiO_2-rich slags containing < 10 % iron is increasing in importance: As these materials contain lower oxides of titanium, they react with chlorine at lower temperatures and require less carbon than rutile [60]. However, compared with rutile, problems are caused by the higher iron content of these slags and their alkaline earth metal content. Calcium and magnesium are converted to their chlorides, which are molten at the reaction temperature and coat the surface of the briquettes in the fixed-bed process, preventing chlorine from penetrating. In the fluidized-bed process, the continuous addition of an inert bed (sand) can give good gas distribution and dilution of the chlorides, so that with continuous removal of residues, slags containing up to 6 % calcium or magnesium can be treated.

The use of other reducing or chlorinating agents (CO, $COCl_2$, CCl_4, sulfur chlorides) and other methods of producing $TiCl_4$ has not achieved industrial importance. For example, the electrolysis of a chloride melt using titanium carbide anodes has been proposed [61]. The most promising process seems to be to digest ilmenite with sulfuric acid and precipitate potassium hexachlorotitanate from the sulfate solution after removal of iron. On heating, this decomposes to form $TiCl_4$ vapor and KCl, which is returned to the process [62].

Figure 2. Purification of crude titanium tetrachloride

Separation and Purification of Titanium Tetrachloride. In the chlorination of rutile, the reaction products are gaseous, consisting of $TiCl_4$ and CO, with small amounts of CO_2, phosgene ($COCl_2$), and other metal chlorides (Fig. 2).

The gases leaving the chlorination reactor are cooled by heat exchangers and by spraying with titanium tetrachloride, and the iron(III) chloride that precipitates at 150 °C is scrubbed out by the $TiCl_4$ [63]. Further cooling causes the titanium tetrachloride to condense. The yellow filtered product contains 94 % $TiCl_4$, ca. 4 % solid constituents such as rutile, carbon, sulfur, and insoluble metallic chlorides, and 2 % soluble metal oxide chlorides. The chlorides include $SiCl_4$ and $SnCl_4$ (low-boiling substances), $VOCl_3$ which has a similar boiling point (127 °C) to $TiCl_4$ (136 °C), and $FeCl_3$ and $AlCl_3$, which have higher boiling points. Other high-boiling chlorides, e.g., of calcium, manganese, magnesium, and sodium, produce unwanted deposits in the equipment.

To purify $TiCl_4$ (→ Pigments, Inorganic, Chap. 2.1.3.3.), the solid constituents are first allowed to settle out. Small amounts of water are added to precipitate aluminum as its oxide chloride. $SiCl_4$ and $SnCl_4$ are removed by distillation at < 136 °C. H_2S is passed in and copper powder is added at 90 °C to reduce $VOCl_3$ to $VOCl_2$, which precipitates. $FeCl_3$ and $AlCl_3$ distil at > 136 °C. Unsaturated organic compounds, especially oleic acid, promote good separation of chromium and vanadium oxychlorides [64].

Dissolved chlorine can be removed by simply heating or by heating with metal powders (iron, copper, or tin). Purification with H_2S can also be carried out continuously in a fluidized bed of silica sand or iron sulfide at 140 – 300 °C. The impurities then form solid products which can be continuously removed from the fluidized bed.

The purified titanium tetrachloride contains only 0.002 % V_2O_5, and is fractionally distilled to remove residual phosgene and $SiCl_4$. The purity of the $TiCl_4$ is 99.9 % min.

7. Production of Titanium Sponge

The large heat of formation of titanium dioxide (945.4 kJ/mol) combined with the high solubility of oxygen in titanium at high temperatures has so far made it impossible to develop an economic process for the direct reduction of titanium dioxide to low-oxygen titanium metal. The standard industrial processes for the production of titanium metal are therefore based on titanium halides.

7.1. Reduction of Titanium Dioxide

The reduction of titanium dioxide by carbon is only possible above 6000 °C. Using carbon-containing reducing agents, some titanium carbide is formed, even in high vacuum [65, 66]. Reduction by hydrogen in the presence of inert gases leads to mixtures of lower oxides [67]. A more complete reduction of titanium dioxide is only possible with alkaline earth metals, whereby reduction with calcium gives the lowest oxygen content [68]. Using reactions at temperatures of 600 – 1200 °C in a vacuum followed by dissolution of excess calcium and calcium oxide in hydrochloric acid, an oxygen content of 0.1 – 0.3 % in the titanium is obtained [69]. Reduction with calcium hydride at 600 – 700 °C gives titanium hydride, which decomposes at 900 °C into titanium (containing 0.2 % oxygen) and hydrogen [70].

7.2. Reduction of Titanium Halides

When $TiCl_4$ is reduced with hydrogen in an electric arc, subchlorides are formed in side reactions, and this reaction is consequently uneconomic on an industrial scale [71]. The reduction of $TiCl_4$ with calcium is strongly exothermic [72], but this reaction also has not been used commercially.

Reduction of Titanium Tetrachloride with Sodium. In 1910, Hunter succeeded in producing larger quantities of pure titanium by reacting titanium tetrachloride with sodium in an evacuated steel bomb [73].

The Degussa process uses a mixture of oxide-free sodium and potassium at 700 – 800 °C. To prevent overheating (sodium chloride *mp* 797 °C, sodium *bp* 877 °C), molten sodium chloride is first placed in the reactor [74]. Finely powdered sodium chloride at 200 – 620 °C can also be used. Molten sodium is then fed into the

reactor from above, and $TiCl_4$ is blown in from below, together with the inert gas [75].

In industrial plant molten sodium and $TiCl_4$ are fed simultaneously into a steel reactor filled with argon, heated to 650 °C. After the reaction has begun, the temperature can rise to 900 °C. When reaction is complete, more sodium is added and the temperature is raised to 950 °C.

In the two-stage process, $TiCl_4$ is first converted at 235 °C into low-melting sodium titanium chloride compounds and titanium(II) chloride, and is then reduced to titanium and sodium chloride in a second reactor after further addition of sodium. This technique distributes the heat of reaction, and the process is therefore more easily controlled. After size reduction of the reaction product, the NaCl is dissolved in water, and the titanium sponge left behind is centrifuged off and dried.

The Hunter process has been almost completely superseded by the Kroll process. Industrial scale plants are currently only operated in China [76].

Reduction of Titanium Tetrachloride with Magnesium (Kroll process). The reduction of titanium tetrachloride with magnesium

$$TiCl_4 + 2\,Mg \longrightarrow Ti + 2\,MgCl_2$$

was discovered by Kroll [72, 77], and was developed into an industrial process by the Bureau of Mines in Boulder City, Nevada [78]. Magnesium boils at 1120 °C, and magnesium chloride melts at 711 °C. The resulting temperature range and the high purity of magnesium are advantageous for the industrial production of titanium sponge from $TiCl_4$.

The reactor is constructed of plain carbon steel, chromium – nickel steel, and the interior walls are cleaned by brushing, or are titanium coated. The reactor is charged with oxide-free lumps of magnesium and filled with argon, and the magnesium is melted at 651 °C (see flow diagram in Figure 3). When the temperature reaches 700 °C, purified $TiCl_4$ is run in slowly from above or blown in as a vapor, such that a reaction temperature of 850 – 950 °C is established. The titanium sponge is deposited on the reactor walls and forms a solid cake above the molten magnesium. The molten $MgCl_2$ collects beneath the magnesium and is drawn off. The magnesium rises through the porous cake to its surface by capillary action, and reacts there with the gaseous $TiCl_4$.

Figure 3. Reduction of titanium tetrachloride to titanium sponge by the Kroll process (reduction with magnesium)

The temperature must not exceed 1025 °C, to prevent reaction between the titanium and the iron of the reactor, although titanium can pick up iron even below 950 °C. The amounts of $TiCl_4$ reacted are 10 – 15 % substoichiometric amount, as some of magnesium and $MgCl_2$ remain in the titanium sponge. However, an excess of $TiCl_4$ leads to the formation of lower titanium chlorides and iron chlorides, which increases the iron content of the titanium sponge.

The temperature range that can be used in practice is 850 – 950 °C, the lower temperatures giving longer reaction times but purer titanium sponge. After the molten $MgCl_2$ has been removed and the temperature of the reactor contents has fallen below 200 °C, the reaction vessel is opened in a dry room ($MgCl_2$ and titanium chloride are hygroscopic).

The crude titanium sponge is generally purified by vacuum distillation; leaching is now rarely used. Around 98 % of titanium sponge produced is vacuum distilled. Immediately after completion of the reaction a vacuum hood usually is attached to the reduction reactor. At ca. 0.1 Pa (10^{-3} mbar) and 900 – 1000 °C, the metal chloride impurities, mainly magnesium and ti-

tanium chlorides, are distilled off together with magnesium metal while the titanium sponge remains behind.

In the leaching process, the size-reduced sponge is treated with a hot mixture of hydrochloric and nitric acids (8 % HCl, 3 % HNO_3) in tanks or in an inclined rotating titanium drum containing an Archimedean screw. Because of the heat of solution of the $MgCl_2$, cooling must be provided to prevent the temperature from exceeding 25 °C. During leaching, the titanium sponge picks up hydrogen, which can be removed by melting in a vacuum electric-arc furnace with a high-performance vacuum pump.

The process of drilling out the crude sponge from the reactor can be avoided by using a perforated crucible if the level of the molten magnesium is maintained above the perforated base [79]. Removal of the sponge from the perforated crucible can be facilitated by facing it with stainless steel or high-carbon steel sheet.

The reduction reactors, usually gas heated, have titanium sponge capacities between 1.5 and 10 t. Production of 1 kg titanium sponge theoretically requires 3.96 kg $TiCl_4$ and 1.015 kg magnesium, 3.975 kg $MgCl_2$ being formed. However, in practice, only 65 – 70 % of the magnesium takes part in the reduction process. Most of the remainder is recovered in vacuum distillation, whereas it is lost in the leaching process. The magnesium is recovered from $MgCl_2$ electrolytically. The proportion of the titanium sponge that can be used for the production of titanium metal is 75 – 85 %, and the total titanium yield is ca. 98 %. The energy consumption is 30 kWh/kg titanium sponge. The reduction process takes ca. 95 h, and the distillation ca. 85 h.

Variants of the Kroll process, so far not used industrially, are aimed at giving better separation of the sponge from the $MgCl_2$ and at achieving continuous operation. For example, in a ram reactor the sponge is compressed by a ram and is ejected as compact metal from the magnesium chloride bath [80].

The reduction can be carried out under vacuum instead of in an argon atmosphere, and the magnesium chloride can be distilled off immediately after completion of the reaction [81].

The simultaneous injection of $TiCl_4$ vapor and magnesium vapor into a reactor packed with titanium netting at 800 – 1100 °C and ca. 10^{-2} Pa produces pure titanium, which grows as crystals on the netting, while the byproducts (Mg vapor and $MgCl_2$ vapor) distil off [82].

In Japan, a quasi-continuous process is being developed in which the distillation of $TiCl_4$, Mg, and $MgCl_2$ and the melting of a titanium block are performed simultaneously [83]. A production of $\geq$ 500 t titanium sponge per furnace per month is expected.

Comparison of the Sodium and Magnesium Reduction Processes. Both methods are used industrially and produce titanium sponge of sufficiently high purity. Their advantages and disadvantages are as follows:

Sodium has a lower melting point than magnesium and can therefore be transported in the molten state. Reduction with sodium requires only the theoretical quantity, whereas ca. 130 % of the stoichiometric quantity of magnesium is required. With sodium reduction, the titanium sponge is more easily removed from the reactor, as NaCl collects on the reactor walls, while in the Kroll process the sponge builds up on the reactor walls. Sodium chloride is soluble in water and is therefore easily removed from the titanium sponge. This is a more economic method than vacuum purification of the titanium sponge produced by magnesium reduction. The density of magnesium-reduced sponge is 1.0 – 1.2 g/cm^3, (sodium-reduced sponge 0.7 – 0.9 g/cm^3) and it has larger particles than sodium-reduced sponge, which contains a high proportion of fines. Typical figures for the chemical composition of various types of sponge produced by both processes are listed in Table 4. This titanium from the Kroll process has a lower average oxygen content and that from the sodium reduction process, a lower average iron content. The highest purity achieved in the Kroll process so far is reported to be 99.999 % [83].

The costs of reduction with sodium are usually ca. 10 % lower than reduction with magnesium, although the economics of the Kroll process can be improved by using larger reduction reactors, improved vacuum distillation, and higher capacity electrolysis cells for recovery of magnesium. In both cases, batch operation is a disadvantage.

The sponges produced by different processes of chemical reduction, size reduction, and purification differ in hardness, lump size, density, and compressibility, but all are equally suitable

Table 4. Chemical composition (in wt %) of titanium sponge

Reduction process	Maximum hardness (Brinell)	C	N	O	H	Fe	Mg	Na	Cl
Magnesium	95	0.006	0.003	0.045	0.002	0.02	0.03		0.10
	100	0.008	0.005	0.05	0.002	0.04			0.09
	110	0.008	0.005	0.06	0.002	0.05	0.03		0.08
	120	0.008	0.005	0.07	0.002	0.06	0.03		0.09
Sodium	120	0.009	0.004	0.07	0.01	0.016		0.08	0.13
Electrolysis	60	0.003	0.002	0.01	0.003	0.001			0.08
	75	0.013	0.004	0.03	0.004	0.004			0.09
	90	0.018	0.004	0.04	0.004	0.020			0.16

for melting into ingots. Therefore, the reasons for selecting a particular reduction process are mainly economic, e.g., availability and reprocessing of reduction metals, energy costs, and capital costs.

In 1995, ca. 98 % of world titanium-sponge production was by the Kroll process.

Reduction of Titanium Tetrafluoride. Titanium tetrafluoride is easily produced from titanium dioxide and hydrogen fluoride, can be readily purified by sublimation, and, in contrast to titanium tetrachloride, titanium tetrafluoride can also be reduced by silicon. The high-purity titanium so produced contains only 0.009 % silicon [84].

7.3. Thermal Decomposition of Titanium Halides

The oldest process of this type is that of VAN ARKEL and DE BOER in which titanium tetraiodide is decomposed on electrically heated tungsten wires at 1000 °C. If wires or single crystal fibers of titanium are used, tungsten-free titanium of the highest purity can be obtained (as a single crystal in the latter case). The iodine liberated is reacted with crude titanium to regenerate titanium tetraiodide in the same vessel below 200 °C or above 500 °C. Above 200 °C lower titanium iodides (TiI_2, TiI_3) are formed, which only act as titanium carriers above 500 °C because of their low volatility [85]. The process enables titanium of the highest purity to be produced from crude titanium or titanium scrap.

Very high purity titanium can also be obtained by thermal disproportionation of titanium(II) chloride or bromide. By passing $TiCl_4$ vapor over titanium-containing material (titanium scrap, crude titanium, or titanium alloys) at 950–1500 °C, $TiCl_2$ vapor is formed, which condenses and is decomposed at ca. 1000 °C

$$2\,TiCl_2 \longrightarrow Ti + TiCl_4$$

The $TiCl_4$ is fed back to the process [86].

7.4. Electrowinning of Titanium

The high affinity of titanium for oxygen and hydrogen together with its electrode potential ($Ti/Ti^{2+} = -1.75$ V) prevents its deposition from aqueous solution [87]. Hence only molten salt electrolysis can be used.

Titanium dioxide is almost insoluble (0.07–0.02 %) in molten chlorides of alkali metals and alkaline earth metals. It is soluble (ca. 8 %) in sodium and potassium fluorides and in potassium hexafluorotitanate (ca. 14 %) [88]. However, attempts to electrolyze the oxide in halide melts (in analogy to aluminum production) only produced lower titanium oxides [89]. Thus only titanium halides are suitable starting materials for molten salt electrolysis.

Titanium tetrafluoride combines with alkali metal and alkaline earth metal fluorides to form complex hexafluorotitanates. These compounds decompose below their melting points with vaporization of titanium tetrafluoride. They can only be used in molten salt electrolysis as components of a low-melting molten salt bath containing other diluent salts [90]. Special problems arise in molten salt electrolysis with graphite electrodes due to the anode effect. Although this can be counteracted by controlled addition of oxides to the salt bath, oxygen pickup by the titanium metal produced must be prevented by using low temperatures, by separating the anode space from the cathode space, and by avoiding turbulence in the electrolyte [91].

Although *titanium tetrachloride* is insoluble in molten alkali and alkaline earth metal chlorides, stable molten electrolytes can be obtained by using lower titanium chlorides. These can be produced directly from titanium tetrachloride in the electrolytic cell, but they react with the chlorine liberated at the anode to reform titanium tetrachloride, which then evaporates. This can be avoided by using a porous, basket-shaped cathode into which the titanium tetrachloride is fed, as the electrolyte (e.g., an $NaCl - SrCl_2$ eutectic) can then be kept free of lower titanium chlorides [92, 93].

The problems of electrolyte composition and the anode effect can be completely solved by using soluble anodes, as in this case no changes to the electrolyte occur and no gas is emitted at the anode, at least at low current densities [94]. Soluble anodes can be made of crude titanium, titanium scrap, and titanium compounds such as titanium carbide, sometimes mixed with titanium monoxide [95, 96] and titanium nitride [97], which can be produced directly from titanium ores.

Semitechnical plants using processes analogous to the production of magnesium from magnesium chloride can operate at 900 °C under argon, using $TiCl_4$ and NaCl as starting materials. The NaCl fed into the cathode space is decomposed, and the sodium liberated reduces the $TiCl_4$ (which is fed in later) stepwise via $TiCl_3$, $TiCl_2$, and TiCl to give titanium. The energy consumption is only 40 % of that required for the reduction of $TiCl_4$ with magnesium (ca. 43 kW h/kg) [98].

All electrolytic processes yield a very pure metal (> 99 % titanium), but have the disadvantage that the titanium is produced at the cathode in the form of poorly adhering dendritic crystals. The cathodes must be lifted out of the molten electrolyte and cooled in an inert atmosphere. The titanium metal is then scraped off and removed from the electrolytic cell through an air lock.

A production plant, now shut down, to produce titanium sponge electrolytically operated at 520 – 650 °C with an electrolyte consisting of a mixture of LiCl and KCl of approximately eutectic composition and with $TiCl_4$ as the raw material. The titanium concentration in the electrolyte is ca. 1.5 %. The $TiCl_4$ is fed through a steel tube into the molten electrolyte in a metal crucible. The graphite anode is surrounded by a wire mesh coated with cobalt or nickel. Metallic titanium is deposited on steel cathodes. After size reduction, dissolution of the salt in 0.5 % hydrochloric acid, washing, and drying, the titanium yield is ca. 98 % [99].

A number of attempts have been made to produce titanium by electrolytic processes on an industrial scale but none have led to permanent application [76].

8. Processing and Reuse of Scrap Metal

With increasing titanium production, the use of titanium scrap as a raw material instead of titanium sponge has become increasingly important. Titanium scrap is produced during the production of semifinished products, their processing to finished products, and the scrapping of used equipment. Before remelting, titanium scrap must be pretreated. Adhering scale and other residues must be removed from the surface by abrasive blasting, pickling, or surface grinding. The various alloys must be sorted so that the alloy added to the melt is of consistent quality. Depending on the melting process, the scrap may be mixed with the sponge and compressed, or may be welded together for addition in the form of a consumable electrode. Alternatively, it can be directly added to the melt in small pieces. In another process, ground, hydrogenated titanium scrap is used instead of titanium sponge for melting to obtain titanium.

Untreated titanium scrap is used as an additive to steel, nickel, aluminum, copper, and zinc alloys, and in the production of master alloys such as ferrotitanium.

In the United States, ca. 40 % of titanium consumption is from processed titanium scrap. In Europe, due to the low price of titanium sponge only 10 – 30 % is accounted for by scrap [100, 101].

9. Processing of Titanium Sponge

Melting Processes. Titanium reacts in the molten state with air and with all the conventional crucible materials. Melting is therefore

only possible under vacuum or in an inert gas atmosphere in cooled metal crucibles of high thermal conductivity, usually copper. The crucible walls are cooled with water or molten sodium–potassium alloy. The energy source is chiefly an electric arc, although to an increasing extent the metal is melted by a plasma, by electron beams, or, on the laboratory scale, by induction.

On the industrial scale, vacuum arc furnaces are generally used, with consumable electrodes made of titanium sponge, titanium scrap, and alloy components. Vacuum arc furnaces with rotating water-cooled copper electrodes are only used for first stage melting.

To produce consumable electrodes, titanium sponge, sometimes mixed with scrap and alloying components, is compressed to form electrode pieces, which are welded into electrodes, by plasma or MIG welding. Large pieces of scrap can also be welded together to form electrodes.

The melting of the electrode (negative pole) takes place when the arc is formed with the bottom of the crucible under argon or a vacuum of ca. 1 Pa (10^{-2} mbar), with currents of 15 – 40 kA and an average melting capacity of 1 kg/kWh. The solidified titanium is remelted in a similar manner, as this gives improved homogeneity. For special applications involving critical service conditions, the titanium is melted three times.

Vacuum arc with solid negative electrodes [102] and cold-hearth melting furnaces with electron-beam (EBCHM) [103] or plasma heating (PCHM) [104] do not require consumable electrodes. The sponge and scrap in lump form are melted by feeding them continuously into the molten metal. These furnaces have so far only been used for the first melt. In cold-hearth melting, sponge and processed scrap are melted in a pre-crucible. The melt is fed into the mold through a channel, whereby impurities can be retained in the skull – the solidified surface forming on the melt in the channel. This method is expected to give better retention of impurities from the scrap. The mold can be designed for producing ingots or slabs. Multiple burners are employed to obtain a continuous ingot or slab. The crucible is equipped with a withdrawable bottom, and the crude ingot is melted to form a strand which is lowered at a rate corresponding to the melting process.

The commercial crude ingots produced by melting can have a mass of 1 – 13 t, but are usually in the range 3 – 8 t. Diameters are in the range 500 – 1100 mm.

Casting. When arc furnaces with consumable or solid electrodes are used [105], the titanium drains into water-cooled tilting copper crucibles, or the melt is superheated by electric current under an inert gas. The metal is cast in graphite, ceramic, or metallic molds, or by centrifugal casting. Electron-beam furnaces can also be used [106]. Depending on the process, the mass of a casting can range from 750 kg to a few grams in the case of high precision castings with small wall thicknesses produced by the lost wax process. The output of titanium castings is barely 1 % of the total output of semifinished products. In a new melting process a combination of cold-wall crucible and plasma burner is used.

Powder Metallurgy. The production of components from titanium and titanium alloys by powder metallurgy has so far not achieved industrial importance. Production of powder by sieving the fine material from titanium sponge or by supersaturating the sponge with hydrogen, milling under inert gas, and dehydrogenation [107] are not widely used because of the poor flow properties of the powder obtained. These properties can be improved by partial melting of the powder to give spheroidal particles.

Spheroidal powder with good flow properties and good densification behavior can also be produced by an atomization process in which titanium rods are rotated at high speed in an electric arc or plasma [108].

Advances in cold-wall crucible technology have now made possible inert gas atomization with argon or helium in a ceramic-free process [109]. Fine, spheroidal titanium powder can be produced by the induction drip-melting atomization process and by the electrode-induction-melting, gas-atomization process.

In the calciothermic production of titanium alloys in powder form, the starting materials are the metal oxides, CaO, Ca, and $KClO_4$. Fine powders with good densification properties (60 %) and with oxygen contents of 0.14 – 0.18 % and carbon contents of 0.03 – 0.06 % [110] are obtained.

Table 5. Composition and strength properties of commercial titanium alloys at room temperature (minimum values)

Alloy∗	Alloy type	Tensile strength, MPa	0.2 % Yield strength, MPa	Density, g/cm^3	Modulus of elasticity, GPa	Main requirement
Ti 5 Al 2.5 Sn	α	830	780	4.48	110	high strength
Ti 6 Al 2 Sn 4 Zr 2 MoSi	near α	900	830	4.54	114	high temperature strength

10. Production and Processing of Semifinished Products

Semifinished products are chiefly produced by pressing, forging, rolling, or drawing.

Hot Forming. In hot forming, the temperature of the metal is above its recrystallization temperature. A slightly oxidizing atmosphere and a uniform temperature are maintained in the reheating furnace to prevent hydrogen pickup and consequent embrittlement. In hot rolling, temperatures are usually 20 – 100 °C below those used for forging.

For pressing or forging heavy section components, a preforming stage is carried out in the β-range, and the final is then carried out, usually in the $(\alpha+\beta)$-range sufficiently below the $(\alpha+\beta)/\beta$-interphase, with deformations of at least 60 – 75 % to produce the desired structure and properties of the material.

Cold Forming. In cold forming to produce wire, thin sheet, and foil, the high yield strength of titanium, which increases with increasing tensile strength, and the low elongation without necking must be taken into consideration. Commercially pure titanium should be work annealed after 30 – 40 % deformation.

Heat Treatment after Deformation. Low-strength titanium (Grade 1, DIN designation 3.7025) generally does not require stress-relief annealing, but annealing is necessary for higher strength and especially complex components.

Recrystallization annealing to give a ductile product is required after hot forming of semifinished and drop forged products, and for work annealing after forming of sheet.

Descaling and Pickling. Titanium is descaled by abrasive blasting followed by pickling in aqueous mixtures of 20 – 40 % HNO_3 and 1 – 3 % HF, in sodium hydroxide-based salt baths with added oxidizing agents such as sodium nitrate and borax at 450 – 510 °C, or in sodium hydride baths at 380 °C. Hydrogen pickup can occur if the pickling time is too long.

Processing of Semifinished Products. Of the noncutting forming processes, deep drawing can be used with titanium-based materials, but stretch-forming is less suitable. In cutting, stamping, pressing, and hole punching, titanium behaves like steel. To give crack-free bending, folding, and edging, radii should be large and deformation rates small. The use of load-bearing lubricants and plastic coatings gives improved drawing behavior [111].

In machining, the low thermal conductivity, low specific heat capacity, low modulus of elasticity, and high toughness lead to considerably higher temperatures in the contact zone than with steel under similar cutting conditions. Also, because of the small extent of chip compression, the contact zone is restricted, leading to additional thermal stress on the tip of the tool. For

low heat generation at the tool a high cutting speed, a low chip removed rate, and sufficient cooling should be provided.

Chemical and electrochemical machining of mechanically machined surfaces are widely used processes, and give high accuracy. Hydrofluoric acid, usually with additions of nitric or chromic acid, is used for chemical machining, while electrochemical machining is carried out with direct current in a solution of NaCl.

Welding. In principle, titanium of all strength grades is weldable. However, it can only be welded with exclusion of air or in an inert gas atmosphere because hot solid or molten titanium reacts readily with the atmosphere, reducing toughness and causing embrittlement, even with low levels of pickup. Electron-beam welding is limited to special applications, particularly the aerospace industries, but MIG, TIG, plasma, and laser-beam welding are widely used (→ Welding and Cutting). Friction and diffusion welding can also be employed with titanium.

Soldering is only possible if a solderable coating is first applied to titanium. For brazing, the dense passive layer on the titanium must first be removed by a flux, which usually consists of alkali metal halides with addition of AgCl. Suitable solders include silver, titanium – silver, and aluminum – silver alloys. It is preferable to solder in a vacuum or in an inert gas atmosphere to minimize diffusion of atmospheric gases into the metal [112]. Soldered joints can have a tensile strength of $> 800\,\mathrm{N/mm^2}$ and a shear strength of ca. $150\,\mathrm{N/mm^2}$.

Adhesives. Adhesive bonds with shear strengths of $> 200\,\mathrm{N/mm^2}$ can be produced if the titanium surface is pretreated and anodically oxidized or coated with metals by spraying or vapor deposition [113, 114].

Explosive Cladding. Industrial low-strength grades of titanium can be applied to metallic substrates, usually steel, by explosive cladding at ca. 5000 MPa, giving shear strengths of ca. $300\,\mathrm{N/mm^2}$. To prevent diffusion between the parent metal and the coating leading to embrittlement of the bonding zone, the upper limit of the usage temperature should be 550 °C [115]. Other substrate metals such as aluminum, copper, and zirconium can also be explosively cladded.

Super Plastic Forming (SPF). Alloyed titanium with a two-phase fine structure often exhibits ductility properties that allow ca. 1000 % elongation. In combination with diffusion welding, highly complex structural components can be produced in a single operation [116].

Tribology. In general, the surface of titanium components is not very resistant against wear. Therefore, wear resistant films are formed by ion implantation or by PVD or CVD. In-situ formation of titanium nitride, carbide, or boride films of varying thickness is achieved by annealing under the corresponding atmosphere or by laser melting [117–121].

11. Titanium Alloys

The main aim of adding alloying elements to titanium is to improve its mechanical properties. The most important of these alloys are listed in Table 5.

The increase in corrosion resistance caused by addition of 0.15 % Pd and traces of Ni and Mo has been mentioned in Chapter 4. Titanium master alloys are discussed in Chapter 13.

11.1. α-, $(\alpha+\beta)$-, and β-Alloys

The transformation temperature of titanium from the α- to the β-phase can be raised or lowered by adding alloying elements which can stabilize the α- or β-phase. Oxygen, nitrogen, and carbon, which form interstitial mixed crystals, and aluminum, which dissolves as a substitution mixed crystal, stabilize the α-phase. Elements that stabilize the β-phase include hydrogen, which forms an interstitial mixed crystal, the alloying elements vanadium and molybdenum, and iron, chromium, copper, palladium, and silicon, while zirconium and tin are highly soluble in both phases.

The alloys are classified as α-, $(\alpha+\beta)$-, and β-titanium alloys according to the phases present in the annealed state at room temperature.

As the cubic structure of β-titanium contains considerably more slip planes than the hexagonal α-form, β-titanium is more easily deformed. The alloys in the β- and $(\alpha+\beta)$-regions are therefore hot formed. β-Alloys and some $(\alpha+\beta)$-alloys contain, in addition to molybdenum or vanadium, additives whose β-phase at temperatures in the range between $< 550\,°C$ and up to a maximum of $860\,°C$ undergo eutectoid decomposition into the α-phase and an intermetallic compound. This process is usually associated with embrittlement and reduces thermal stability and must be avoided during production and processing.

The critical alloying content of β-stabilizing elements in two-component alloys in which the β-phase is preserved on quenching to room temperature and the eutectoid data for alloys showing eutectoid decomposition are listed in Table 6. Also, many two- and multi-component phase diagrams can be found in [122].

Table 6. Eutectoid temperature and critical alloy content of titanium binary alloys (concentrations in wt %)

	Eutectoid composition	Eutectoid temperature, °C	Critical alloy content
Manganese	17	550	6.4
Iron	17	595	3.5
Chromium	15	670	6.3
Cobalt	9.5	685	7.0
Nickel	6.2	765	9.0
Copper	7	790	13.0
Silicon	0.65	865	
Vanadium			14.9
Molybdenum			11.0
Niobium			36.7
Tantalum			45.0

The equilibrium state is established very slowly for many alloy systems at lower temperatures. For systems showing eutectoid decomposition of the β-phase, the process proceeds more slowly at lower temperatures and with higher alloy contents of the eutectoid. This is especially noticeable in multicomponent alloys [123].

Hardening of titanium alloys can be carried out in various ways: An intermetallic compound can be precipitated from the α-phase by quenching and annealing (e.g., with Ti – Cu alloys). In alloys with β-stabilizing alloying elements, the supercooled metastable β-phase can be formed in addition to the α-phase by solution annealing, quenching, and aging. On aging, the former is transformed via an intermediate ω-phase into the α-phase and to β-phase stabilized by enrichment of the alloying elements. Both these processes are used in industry to improve the mechanical properties of titanium alloys.

Mechanical Properties. The strength properties of the most important titanium alloys are listed in Table 5.

The α-alloys, which have a strength range of 830 – 1030 MPa, are used as forging alloys, and also in the production of sheet metal because of their good welding properties. Ti 5 Al 2.5 Sn has good high-temperature tensile strength. The near α-alloys are members of the group of high-temperature titanium alloys, used in aircraft engines.

The $(\alpha+\beta)$-alloys include the most common titanium alloy Ti 6 Al 4 V. Its strength of 900 MPa in the annealed state can be in-creased by ca. 200 MPa by hardening. Strengths exceeding 1000 MPa with better through hardenability can be obtained with the alloys Ti 6 Al 6 V 2 Sn and Ti 4 Al 4 Mo 2 Sn.

β-Alloys with a strength of 1000 – 1200 MPa in the annealed state include Ti 15 V 3 Cr 3 Sn 3 Al, Ti 3 Al 8 V 6 Cr 4 Zr 4 Mo and Ti 15 Mo 3 Nb 3 AlSi. These are mainly used as sheet alloys in aircraft construction [124].

The through hardening properties of the alloys Ti 6 Al 6 V 2 Sn and Ti 4 Al 4 Mo 2 Sn are superior to those of the usual commercial titanium alloys. These alloys are also preferable to Ti 13 V 11 Cr 3 Al, as they have better figures at > 100 mm, the latter alloy tending to have a coarse-grained structure and poor toughness properties.

The fatigue strength of titanium alloys depends on the section of the semifinished product and its structure. In the unnotched state, it is 30 – 50 % of the tensile strength, and in the notched state 30 %. The fracture toughness of metal with a Widmannstätten structure reaches higher values than that of metal with a polygonal structure [125].

The rate of decrease of high-temperature tensile strength of alloys with increasing temperature up to ca. 250 °C is lower than that of commercially pure titanium, and the creep strength figures are higher.

The ratio yield point is > 90 %. As the elongation without necking is small, these materi-

als are usually hot formed. Solution annealing and stabilization give improved properties, e.g., increased thermal stability and improved creep properties.

In Germany, materials standards for titanium and titanium alloys are given in a number of DIN standards, materials performance sheets (Werkstoffleistungsblätter, WL), and AECMA/EN standards. In France, this information is provided by AFNOR (Association Française de Normalisation) and NORME AIR of the Ministère de la Défense, in the United Kingdom by the British Standards Institution (BSI) and the DTD of the Ministry of Defence, and in the United States by ASTM, ASME, AMS, and MIL of the Air Force Materials Laboratory.

Physical Properties. In the commercial α- and $(\alpha+\beta)$-titanium alloys, the density at 25 °C is in the range 4.37 – 4.56 g/cm^3. In β-titanium alloys, values of 4.94 g/cm^3 are reached. Moduli of elasticity and rigidity increase with increasing content of interstitial elements and aluminum, and with annealing temperature [126]. With additions of β-stabilizing additives, they decrease in comparison with pure titanium, as hardening increases [25]. With both pure titanium and commercial titanium alloys they decrease with increasing temperature [23]. At 25 °C titanium alloys usually have electrical resistivities of ca. $150\times10^{-6}\,\Omega$ cm. The linear coefficient of expansion at 25 °C for α- and $(\alpha+\beta)$-titanium alloys is ca. $9.5\times10^{-6}\,K^{-1}$. The specific heat capacity is similar to that of titanium, and is somewhat higher for $(\alpha+\beta)$-titanium alloys. The thermal conductivity is only half that of titanium.

Chemical Resistance. Additions of noble metals and other metals such as molybdenum, zirconium, hafnium, nickel, tantalum, or niobium improve the anticorrosion properties of titanium, while additions of iron, chromium, and aluminum, like high levels of oxygen, nitrogen, and hydrogen, reduce corrosion resistance [51].

The corrosion behavior of commercial titanium alloys is very similar to that of the commercially pure metal. Unlike titanium containing 0.15 % Pd, alloys containing 2 % Ni or 15 – 30 % Mo [127] have not achieved industrial importance, in spite of their superior corrosion resistance under reducing conditions.

With increasing aluminum content, the susceptibility of titanium alloys to stress corrosion cracking at >200 °C increases [128].

11.2. Highly Alloyed Titanium

Intermetallic Ti – Al Alloys. Three intermetallic titanium aluminides are known: Ti_3Al, TiAl, and $TiAl_3$ (Fig. 4). In particular, the phases α_2-Ti_3Al (hexagonal) and γ-TiAl (tetragonal) exhibit low density and good high-temperature strength and were therefore chosen for development of construction materials. The main aims are increasing the room-temperature ductility of these brittle phases and improving the corrosion resistance in the temperature range 500 – 900 °C [130, 131].

The α_2-Ti_3Al alloys were developed in the United States and first used commercially in the 1990s. They mainly replace conventional titanium alloys, allowing applications above 500 °C. The ductility is increased by alloying with 8 –18 wt % Nb. Other possible alloying elements are Mo, V, Ta, and Ni. In addition to Ti_3Al, the phases β-NiAl (cubic) and Ti_2AlNb can also be present [132]. Characteristic data of α_2-Ti_3Al can be found in [133]. α_2-Ti_3Al is produced by melting in vacuum arc furnaces.

γ-TiAl alloys have been under development for around ten years and are now on the brink of commercial application. They can be used up to 850 °C, and with their density of 3.9 g/cm^3, they could potentially replace nickel superalloys in aircraft and turbines [134, 135]. Another potential application is as a valve material for combustion engines [136]. γ-TiAl alloys consist of two phases: γ-TiAl (tetragonal face-centered $L1_0$ structure) and a small amount of α_2-Ti_3Al (hexagonal DO_{19} structure) [137]. The aluminum content is 45 – 48 % Cr. H, Mn, and V are added to increase the room-temperature ductility, while Nb, Ta, Mo, and W improve the high-temperature creep resistance and corrosion resistance. Si, B, and C can be used as grain refiners. The total content of alloying elements is usually in the range 2 – 7 % [137].

Two-phase γ-TiAl materials can be produced by powder metallurgy [138] or by melting in vacuum arc furnaces.

Figure 4. Ti – Al phase diagram [129]

Table 7. Properties of titanium aluminides, titanium-base conventional alloys, and nickel-base superalloys ∗

Property	Conventional titanium alloys	Ti_3Al	TiAl	Nickel-base superalloys
Density, g/cm^3	4.5	4.1 – 4.7	3.7 – 3.9	8.3

at room temperature	20	2 – 10	1 – 4	3 – 5
at high temperature	high	10 – 20	10 – 60	10 – 20

∗ From *ASM Handbook*, 10th. ed., vol. 2, ASM International, Metals Park, OH, 1990, p. 226.

Table 7 compares the properties of titanium aluminides with those of conventional titanium alloys and nickel superalloys [139].

Shape-Memory Alloys. Ti – Ni alloys containing ca. 50 atom % Ni exhibit an austenite – martensite transformation at a definite temperature. Depending on the type of activation used (working at a certain temperature), either a shape-memory effect is obtained, or superelasticity [140].

Superconductors. Ti – Nb alloys containing ca. 50 atom % Nb are low-temperature superconductors with good ductility, high critical field strength, and high critical current (→ Superconductors, Chap. 5.2.1.). Wires of ca. 5 µm diameter can readily be made into coils [141].

Metal-Matrix Composites. The tensile strength, especially at high temperatures, of titanium alloys can be increased by strengthening the metal matrix with fibers such as SiC [142].

Hydrogen Storage. Titanium alloys with high contents of Fe, Cr, Mn, and V can take up large amounts of hydrogen, which is released under certain conditions of temperature and pressure. They can therefore be used for hydrogen storage, as in gas purification, and for vacuum generation [143].

12. Uses and Economic Aspects

Chemical Industry. In chemical plant, commercially pure and palladium-containing titanium lead to increased lifetime, reduced maintenance, and reduced iron contamination of products. Important applications include petrochemicals and the production and handling of, e.g.,

acetic acid, propionic acid, nitric acid, and chlorine gas. Titanium is used in all types of chemical equipment, including pressurized reactors. The temperature limit for equipment constructed of pure titanium is usually 250 °C, for titanium-clad equipment 200 °C, and for titanium-plated equipment ca. 500 °C.

In the food industry, cooking equipment, stirring devices, and containers are constructed of titanium because of its resistance to a wide range of organic acids. In the cellulose, paper, and textile industries, titanium is important because of its resistance to hypochlorite, chlorite, and chlorine dioxide. In deep-sea research, seawater desalination, and closed-loop cooling water systems in power stations, the good resistance toward salt water even at high flow rates and at temperatures up to 165 °C (e.g., in tube and plate heat exchangers) is utilized. In electrolysis technology and surface finishing, commercially pure grades of titanium, especially the softer grades 3.7025 (Grade 1) and 3.7035 (Grade 2), are used for a wide range of components including anodes (sometimes platinum-coated and cathodes [52, 144]. Offshore and onshore drilling represent a growing demand for titanium.

Aerospace. The largest consumer of titanium alloys is the aircraft industry, in which the nonmilitary share continues to increase. In aircraft engines, the current limit for weight saving by the use of titanium lies at Mach 3.5 and ca. 530 °C. In subsonic engines, the titanium content is 20 – 35 %, and the weight saving achieved is up to 22 % [145].

In airframes, temperatures of 300 °C are seldom exceeded. With increasing flying speed, the weight saving achievable by the use of titanium can reach ca. 17 %. In civilian wide-body jets, the proportion of titanium-based materials in the body of the aircraft can reach 8 %, and in military supersonic aircraft 25 % or more. Unalloyed grades of titanium are used for lightly stressed components, and alloys for highly stressed components.

Other Applications. Applications in the automotive industry include components of high-performance engines and undercarriage made of titanium alloys [146]. Pure titanium is used as a getter in electronic tubes used in the measurement, control, and electrical technologies, X-ray amplifiers, television cameras and transmitter tubes, and in sonar detectors and gyrocompasses. In medicine, endoprostheses, jaw implants, pins for fixing broken bones, plates, heart pacemaker capsules, and surgical instruments are manufactured from titanium and the alloy Ti 6 Al 4 V because of their compatibility with human tissue.

Applications in precision engineering and optics include sonotrodes, rotors for ultracentrifuges, spectacle frames, watches, golf clubs, and film-developing equipment. Titanium has so far not been widely used in steam turbines, although it is suitable. The same applies to its use in underwater exploration and submarine construction.

Economic Aspects. At present, titanium sponge is produced in the United States, Japan, Russia, Kazakhstan, China, and India. World production capacity for titanium sponge in 1994 was 113 300 t. An overview of the producing countries and existing capacities for sponge and ingot production is given in Table 8. Ingot production capacity in Western Europe, the United States, and Japan reached ca. 85 000 t in 1994.

Table 8. Production capacities for titanium sponge and melting capacities in 1994

Country	Capacity, t/a	
	Sponge	Ingots
United States	19 500	57 700
Japan	25 000	22 400
Europe		9 500
CIS	65 000	110 000
China	3 000	3 000
Total	113 300	202 600

Worldwide consumption of titanium semifinished products in 1994 was ca. 45 000 t. European demand in 1994 was ca. 10 000 t, expected to reach 13 300 t in the year 2000.

13. Titanium Master Alloys

13.1. Ferrotitanium

13.1.1. Composition and Uses

Ferrotitanium is described in DIN 17 566 as a master alloy containing at least 28 wt % Ti, obtained by reduction of the corresponding raw

Table 9. Composition of commercial ferrotitanium alloys from DIN 17 566

Alloy grade	Alloy number[a]	Chemical composition, wt %						
		Ti[b]	Total Al max.	Si max.	Mn max.	C max.	P max.	S max.
FeTi 30	0.4530	28 – 32	4.5	4.0	1.5	0.10	0.050	0.060
FeTi 40	0.4540	36 – 40	6.0	4.5	1.5	0.10	0.10	0.060
FeTi 50	0.4550	46 – 50	7.5	4.0	1.0	0.10	0.10	0.060
FeTi 70	0.4570	65 – 75	2.0	0.20	1.0	0.20	0.040	0.030
FeTi 70 VB (vacuum treated)	0.4571	65 – 75	0.50	0.10	0.20	0.20	0.030	0.030

[a] In accordance with DIN 17 007, Sheet 3 (draft);
[b] Variation within a batch must not exceed ± 2 wt %.

materials or their concentrates. The International Standard for ferrotitanium is ISO 5454-1980 (E), which specifies a Ti content of at least 20 wt % and allows greater variation in the Al content (up to 10 wt % Al) than DIN 17 566. The Standards specify not only the chemical composition (see Table 9) but the condition, testing methods (sampling and analysis), shipping, and storage. Ferrotitanium in "normal lump form" usually means lumps up to 25 kg in weight. Ferrotitanium can also be supplied on demand as crushed material and/or sieved as agreed. It is supplied in sealed steel drums.

Melting points and densities of some commercial ferrotitanium alloys are listed in Table 10.

Table 10. Melting points and densities of some commercial ferrotitanium alloys

Composition, wt %			*mp*, °C	ϱ, g/cm^3
Ti	Al	Si		
30.6	4.0	3.7	1325 – 1500	6.2
39.1	5.8	4.0	1325 – 1480	5.9
46.6	7.6	3.2	1305 – 1480	5.5
70.0	0.1 – 0.5		1070 – 1135	5.4

The binary titanium – iron phase diagram is shown in Figure 5 [147].

Applications in the Iron and Steel Industry. Compared with pure titanium, ferrotitanium has the advantages of better solubility (lower melting point and higher density) and lower price. Titanium is useful mainly because of its ability to form a carbide. However, as the affinity of titanium for oxygen is considerably higher than for carbon, the steel must be effectively deoxidized before titanium is added. Titanium is only used for this deoxidation in special cases. Titanium is also used for nitrogen removal and for bonding with sulfur [148].

In the production of stainless austenitic chromium – nickel steels, titanium is added to combine with the small amount of carbon present to form TiC ("stabilization"), thereby preventing intergranular corrosion (e.g., adjacent to welds).

Deoxidation of killed steel with titanium improves its quality by minimizing oxidic inclusions. Depending on the carbon content, it also reduces cracking tendency (grain refinement of austenite) and increases yield strength (titanium-containing ferrite). Titanium addition also minimizes segregation in the upper part of the ingot on casting, thus improving the yield.

Addition of titanium to tool steels gives a finer grain and reduces the depth of hardening and hence the cracking tendency. In sulfur-containing free-cutting steels, especially highly alloyed stainless chrome and chromium – nickel steels, the sulfur is bonded to the titanium. This prevents red shortness and improves ductility.

Some complex master alloys with boron (→ Boron and Boron Alloys, Chap. 2.4.2., → Boron and Boron Alloys, Chap. 2.5.) contain titanium and other elements (BATS = boron – aluminum – titanium – silicon). The boron is added in small amounts to the steel to improve the hardening properties and grain refinement, and the titanium is added to protect the boron from nitrogen (by forming TiN).

High-temperature hardenable alloys (superalloys, → High-Temperature Materials) based on iron and especially nickel (e.g., nimonic alloys) contain up to 4.5 % Ti [149]. Here, the titanium reacts with the aluminum and nickel to form coherent particles with the composition $Ni_3(Ti, Al)$, which cause precipitation hardening. Titanium is also used as a microalloying el-

Figure 5. Ti – Fe phase diagram [147]

ement in high-strength, low-alloy (HSLA) steels [150].

The addition of titanium to cast iron causes the formation of finer graphite on supercooling, thereby improving the mechanical properties.

Powdered ferrotitanium and ferrosilicon – titanium alloys, sometimes with higher aluminum contents, are used as coatings on welding electrodes. Also, welding wires for HSLA steels are alloyed with ca. 0.5 % Ti to give a fine-grained weld bead.

13.1.2. Production

The starting materials for the production of ferrotitanium are ilmenite, leucoxene, perovskite, and slag concentrates produced from ilmenite. Because of the increasing availability of titanium scrap, this also is used to an increasing extent for the production of ferrotitanium (mostly > 70 % Ti) and other titanium master alloys.

Reduction with Carbon. Carbothermic production in electric-arc furnaces leads to high carbon contents in the ferrotitanium. However, as the main use of ferrotitanium is to combine with the carbon in steel, the presence of carbon in the ferrotitanium is undesirable, and this production method is therefore now hardly used. The carbothermic production of ferrotitanium containing 15 – 18 % Ti, 5 – 8 % C, 1 – 3 % Si, and 1 – 2 % Al, and of ferrosilicon – titanium containing ca. 30 % Ti, ca. 30 % Si, up to 0.3 % C, and 1 – 3 % Al is described in [151].

Metallothermic Production. DIN 17 566 specifies grades of ferrotitanium containing 28 – 50 wt % Ti and 4.5 – 7.5 wt % Al. These are mainly produced by the aluminothermic process. The reduction of TiO_2 by Al proceeds via TiO.

$$3\,TiO_2 + 2\,Al \longrightarrow 3\,TiO + Al_2O_3$$

$$3\,TiO + 2\,Al \longrightarrow 3\,Ti + Al_2O_3$$

If there is too much TiO_2 in the reaction mixture, TiO can be formed as a third phase besides the metal and slag [152]. In the aluminothermic production of ferrotitanium there is a high consumption of aluminum, as it reacts both with the iron oxide in the ilmenite and with the oxygen-producing substances added to increase the exothermicity.

An aluminothermic mixture, consisting, for example, of 4320 kg Australian ilmenite (58.55 % TiO_2), 480 kg rutile (96.7 % TiO_2), 190 kg calcined limestone, 107 kg potassium perchlorate, and 1693 kg Al powder, is placed in a refractory-lined combustion vessel and ignited to start the reaction. After cooling, a 2250 kg block of ferrotitanium is obtained containing 39.8 % Ti, 6.7 % Al, 3.4 % Si, and 0.02 % C, which separates well from the slag. The titanium yield is 50 %, and the specific consumption of aluminum (based on the Ti in the ferrotitanium) is 1.89 kg Al/kg Ti.

In the electro-aluminothermic process, which is carried out in an arc furnace, the raw materials contain as little iron oxide as possible, so that most of the aluminum is used to reduce titanium oxide. The consequent lack of exothermicity is compensated by electrical energy. A process developed in France is now widely used [153]. Here, an ilmenite concentrate, after addition of lime, is partially reduced with carbon in an electric-arc furnace to give a slag concentrate with a high concentration of titanium oxide, and the reduced iron is tapped off. The molten slag is then reduced in several stages by blowing in aluminum and iron, producing ferrotitanium of the desired composition.

In a process developed by the Gesellschaft für Elektrometallurgie [154], a calcium oxide/titanium oxide melt containing ca. 75 % TiO_2 is first produced from prereduced ilmenite, from rutile and lime, or from perovskite with addition of iron scrap, and is reacted with a molten aluminum – iron alloy containing 60 – 70 % Al in a reaction ladle to give ferrotitanium and slag. Yields of titanium of 60 – 67 % are obtained, and the specific aluminum consumption is 1.0 – 1.1 kg Al/kg Ti.

Production from Titanium Scrap and Sponge. As the availability of titanium scrap is increasing with the growth in the consumption of titanium, it is being increasingly used for the production of ferrotitanium (mainly high-grade material containing 65 – 75 % Ti) and ferrotitanium – silicon. Because of its low melting point (ca. 1100 °C), the alloy containing 70 % titanium melts comparatively readily when alloyed with iron in an induction furnace, in an arc furnace with consumable electrodes under vacuum or argon, or in an electroslag melting furnace. Contact of the melt with air must be prevented because of the strong affinity of titanium for oxygen and nitrogen. Ferrotitanium can also react with refractory crucibles [155]. The high-grade ferrotitanium alloys produced by melting under vacuum are designated FeTi 70 VB in DIN 17 566.

Calcium – silicon – titanium alloys are produced by melting together commercial calcium silicon and titanium sponge or scrap in an induction furnace [151, p. 579].

13.1.3. Economic Aspects

The prices of ferrotitanium are published in the London "Metal Bulletin", and the monthly average prices (from the Metal Bulletin), with the corresponding exchange rates, have been published since 1979 in the journal *Erzmetall* [156].

13.2. Titanium – Aluminum

The alloys listed in Table 11, used as master alloys for alloying aluminum with titanium and as grain-refining agents, are standardized in DIN 1725. The master alloys containing 5 – 10 wt % Ti (known in the United Kingdom as titanium – aluminum intermediate hardeners) are produced by melting aluminum and titanium scrap or sponge in crucible or drum furnaces heated by gas or oil, or in induction furnaces. They are cast into pigs, or grooved ingots or plates, and are marketed in these forms.

The alloy V-AlTi 5 B 1, which is used for grain refining aluminum, contains titanium boride (TiB_2) in the form of a very fine precipitate which acts as seed crystals [157]. The alloy is also supplied as wire for continuous grain refinement. It is produced by adding potassium titanium fluoride and potassium borofluoride to a bath of molten aluminum in an induction furnace.

Table 11. Titanium – aluminum alloys according to DIN 1725, Sheet 3

Alloy grade	Alloy number	Composition, wt %			Applications
		Alloy constituents	Other permitted constituents		
V-AlTi 5	3.0851	Ti 4.5 – 6.0 Al to 100	Cr 0.10 Cu 0.15 Fe 0.45 Mg 0.50 Mn 0.35 Ni 0.10 Pb 0.10	Si 0.50 Sn 0.10 V 0.25 Zn 0.15 others : each 0.05 total 0.15	alloying with Ti grain refinement

V-AlTi 5 B 1	3.0861	Ti 5.0 – 6.2 B 0.9 – 1.4 Al to 100	Cr 0.02 Cu 0.02 Fe 0.30 Mg 0.02 Mn 0.02 Ni 0.04 Si 0.20	V 0.20 Zn 0.03 Zr 0.02 others : each 0.05 total 0.10	grain refinement

Titanium – aluminum containing 50 – 60 % titanium can also be produced by the aluminothermic reaction of rutile with aluminum powder with addition of boosters such as peroxides or chlorates, or by the electro-aluminothermic method in an arc furnace. Today, these high-titanium alloys, which are mainly used in powder form as components of welding wire coatings, are also produced by melting together aluminum and titanium in an induction furnace.

13.3. Other Master Alloys

Special master alloys such as copper – titanium (26 – 35 wt % Ti) and nickel – titanium (25 – 70 wt % Ti) are produced by melting titanium sponge or titanium scrap with copper or nickel. These master alloys are used as additives (0.1 – 1.5 % Ti) to copper, nickel, and monel metal to grain refine the structure, improve the casting and welding properties, and increase the transverse strength and elasticity. A small addition of titanium (0.15 – 0.25 %) to zinc alloys containing up to 1.5 % Cu increases the yield strength and fatigue strength [158].

The high coercive field strength and low remanence of AlNiCo permanent magnets are due to the addition of 0.5 – 8 % titanium in the form of AlTi of CoAlTi master alloys (→ Magnetic Materials, Chap. 4.1.1.).

Multicomponent, NiTi-based alloys are employed in powder metallurgy for manufacturing structural materials.

14. Titanium Compounds [159, 160]

Titanium Carbide → Carbides, Chap. 2.2.

Titanium Dioxide → Pigments, Inorganic, Chap. 2.1.

Titanium is usually tetravalent in its compounds, but may also be trivalent and, in a few compounds, bivalent; the compounds of bivalent titanium are prepared only with difficulty and are unstable in aqueous solution. The existance of titanium(I) compounds has not been established, although certain observations point to their formation, e.g., the existence of maximum volatility in the Ti – S system at a composition corresponding roughly to the formula Ti_2S.

Tetravalent titanium has a strong tendency to form anions such as $[TiO_3]^{2-}$ (titanate ion), $[TiF_6]^{2-}$ (fluorotitanate ion), $[TiCl_6]^{2-}$ (chlorotitanate ion), and $[Ti(SO_4)_3]^{2-}$ (sulfatotitanate ion). The soluble titanium(IV) com-

pounds tend to undergo hydrolytic decomposition. Incomplete hydrolysis may give rise to compounds to the type $TiOX_2$. Compounds containing the radical $[TiO]^{2+}$ are called titanyl compounds.

The oxidation potential Ti^{3+}/Ti^{4+} (relative to the normal hydrogen electrode at 0 °C) is +0.04 V. For the couple Ti^{2+}/Ti^{3+} the oxidation potential $E^0 = +0.37$ V, and for the couple Ti^{2+}/Ti^{4+}, $E^0 = +0.20$ V. The normal potential of Ti in contact with a Ti(II) salt solution is +1.75 V.

14.1. Titanium(II) Compounds

Compounds of bivalent titanium can be prepared by reduction of titanium(IV) or titanium(III) compounds. Thus titanium(II) chloride, $TiCl_2$ is produced from titanium tetrachloride by means of sodium amalgam, as a black powder which is slowly decomposed by water with the evolution of hydrogen. Aqueous solutions which contain titanium(II) chloride together with titanium(III) chloride can be prepared by dissolving TiO in cold dilute hydrochloric acid. Ti^{2+} ions are rapidly oxidized to Ti^{3+} ions by water at normal temperature; the solutions are more stable at lower temperatures. In the pure state, $TiCl_2$ is best obtained by thermal decomposition of $TiCl_3$ or by heating $TiCl_4$ with Ti shavings. $TiBr_2$ and TiI_2 can be prepared by direct union of their components.

TiO, ϱ 4.94 g/cm^3, *mp* 175 °C, can be obtained by heating a mixture of TiO_2 and Ti. It has the NaCl type crystal structure, but a certain proportion of the lattice sites (distributed at random) is vacant. At the one end of the homogeneity range, these vacant sites represent missing Ti atoms, and at the other extreme O atoms.

14.2. Titanium(III) Compounds

Titanium(III) compounds are obtained by reducing soluble titanium(IV) compounds with zinc and acid or electrolytically. The solutions contain violet titanium(III) ions; these have a strong tendency to revert to titanium(IV) ions. The ability of trivalent titanium to bring about indirect oxidation by means of oxygen is so great that even water can play the part of an acceptor in the presence of titanium(III) compounds in alkaline solution, and is thereby converted to hydrogen peroxide:

$$Ti(OH)_3 + {}^1/_2O_2 + H_2O \rightarrow TiOH_4 + {}^1/_2H_2O_2$$

Titanium(III) Halides. Anhydrous is obtained as a violet powder by passing titanium tetrachloride vapor and an excess of hydrogen through a red hot tube. When it is heated in hydrogen to about 700 °C, $TiCl_3$ disproportionates into $TiCl_2$ and $TiCl_4$. Titanium(III) chloride is obtained in solution by reducing a solution of titanium(IV) salt in hydrochloric acid by means of zinc, or by dissolving metallic titanium in hydrochloric acid. A violet hexahydrate, $TiCl_3 \cdot 6\,H_2O$, crystallizes from the solution.

Titanium (III) bromide, $TiBr_3 \cdot 6\,H_2O$, forms reddish violet crystals (*mp* 115 °C) which are readily soluble in alcohol and acetone, as well as in water. Anhydrous $TiBr_3$ exists in two modifications. It decomposes reversibly at 400 °C, according to:

$$2\,TiBr_3 \rightleftarrows TiBr_2 + TiBr_4$$

Titanium(III) fluoride, TiF_3, can be obtained as a dark blue powder by treating Ti or $TiCl_3$ with HF. It is very unreactive and begins to sublime at 900 °C in a vacuum.

Titanium(III) sulfates. In the electrolytic reduction of a sulfuric acid solution of titanium(IV) sulfate, a black-violet solution is first obtained. The solution becomes lighter with continued reduction, and when practically all the titanium is converted to the trivalent state, it has a transparent pure violet color. An acid titanium(III) sulfate, with the composition $3\,Ti_2(SO_4)_3 \cdot H_2SO_4 \cdot 25\,H_2O$ can be isolated from the solution in the form of a crystalline violet powder. This can be converted to anhydrous neutral titanium(III) sulfate, $Ti_2(SO_4)_3$, by fuming with sulfuric acid.

Neutral titanium(III) sulfate is a green crystalline powder, insoluble in water but soluble in dilute acid to give violet solutions. Exchange of hydrogen in acid titanium(III) sulfate by metal ions gives rise to double or complex salts,

with the composition $3\,Ti_2(SO_4)_3 \cdot M^I_2SO_4$, or $M^ITi_3(SO_4)_5$ and variable water content, e.g., the ammonium salt $NH_4Ti_3(SO_4)_5 \cdot 9\,H_2O$, which forms blue crystals, sparingly soluble in water. Another type of double sulfate of trivalent titanium corresponds to the alums in composition and crystalline form. The only known titanium alums are the rubidium and cesium compounds, e.g., $RbTi(SO_4)_2 \cdot 12\,H_2O$ (red-violet). These salts can be recrystallized without decomposition from dilute sulfuric acid, but not from water. Yet another type is represented by the sodium double sulfate, a violet crystalline mass with the composition $NaTi(SO_4)_2 \cdot 2.5\,H_2O$.

Titanium(III) Hydroxide and Oxide. *Titanium(III) hydroxide* is formed by reaction of titanium(III) salt solutions with alkali hydroxides as a deeply colored precipitate which acts as a vigorous reducing agent and is therefore difficult to obtain pure.

Dititanium trioxide, Ti_2O_3, ϱ 4.49 g/cm^3, *mp* ca. 1900 °C, can be obtained crystalline by heating titanium dioxide at 1000 °C in a stream of hydrogen and titanium tetrachloride. It has the same crystal structure as corundum.

14.3. Titanium(IV) Compounds

Titanium(IV) Halides.

Titanium tetrachloride [*7550-45-0*], $TiCl_4$, M_r 189.73, *mp* − 23 °C, *bp* 136.5 °C, ϱ 1.76 g/cm^3 at 0 °C, can be obtained by passing chlorine over heated titanium, titanium carbide, or over a mixture of titanium dioxide and carbon. In the pure state, it is a colorless liquid which has a pungent smell, fumes strongly in moist air, and is rapidly hydrolyzed by water:

$$TiCl_4 + H_2O \rightarrow TiO_2 + 4\,HCl$$

If the hydrolysis is supressed by addition of acid or if only a limited amount water enters into reaction, oxychlorides can appear as intermediate products. Titanium tetrachloride adds chloride ions to form the complex chlorotitanate ion $[TiCl_6]^{2-}$, e.g., the ammonium salt $(NH_4)_2[TiCl_6] \cdot 2\,H_2O$ (yellow crystals). The corresponding free acid can only exist in aqueous solution; its formation therein is demonstrated by yellow coloration produced by the addition of concentrated hydrochloric acid to titanium tetrachloride.

Titanium tetrafluoride [*7783-63-3*], TiF_4, M_r 123.90, *mp* > 400 °C, ϱ 2.80 g/cm^3 is prepared by reaction of $TiCl_4$ with HF, forms a white powder that sublimes at 284 °C. It displays a much stronger tendency than does the chloride to form titanates. These correspond to the type $M^I_2[TiF_6]$ (fluorotitanates). All the alkali and alkaline earth salts of this type, as well as numerous salts of the heavy metals have been prepared.

Titanium tetrabromide [*7789-68-6*], $TiBr_4$, M_r 367.56, obtained in similar manner to $TiCl_4$ (as yellow octahedral crystals, ϱ 3.25, *mp* 40 °C, *bp* 320 °C), is similar to the chloride in its chemical behavior. It is extremely hygroscopic, soluble in alcohol and moderately soluble in ether.

Titanium tetraiodide, TiI_4, is prepared by double decomposition of $TiCl_4$ with HI. It crystallizes as red-brown octahedra (*mp* 150 °C, *bp* 365 °C).

Titanyl Sulfate. When titanium dioxide is fumed with concentrated sulfuric acid, titanyl sulfate, $TiOSO_4$, is formed, as a white powder, soluble in cold water. It is decomposed by hot water, with the deposition of gelatinous titanium dioxide:

$$TiOSO_4 + H_2O \rightarrow TiO_2 + H_2SO_4$$

In addition to titanyl sulfate, there are other titanium sulfates, both with higher and lower SO_3 contents. The neutral titanium sulfate, $Ti(SO_4)_2$, is not known with certainty in the free state. Double salts derived from it are known, in particular the sulfatotitanates of the type $M^I_2[Ti(SO_4)_2]$. Titanyl sulfate also forms double salts, e.g., $(NH_4)[TiO(SO_4)_2] \cdot H_2O$.

Titanates. Neglecting their water of crystallization, the alkali titanates correspond mostly to the formulas $M^I_2TiO_3$ and $M^I_2Ti_2O_5$. They can be obtained by evaporating solutions of α-titanic acid in concentrated alkali hydroxide solutions (β-titanic acid is insoluble). They can be prepared in the anhydrous state by fusing titanium dioxide with alkali metal carbonates. The titanates of other metals can also be prepared by high-temperature methods. Compounds of the type $M^I_4TiO_4$ (orthotitanates) are

formed in this way by a few metals, as well as those of the type $M^{I}_{4}TiO_3$ (metatitanates). Numerous polytitanates (compounds with more than one TiO_2 per one $M^{I}_{2}O$) have been obtained by fusion methods. Alkaline earth metal titanates are known corresponding to the types $M^{II}TiO_3$, $M^{II}_{2}TiO_4$, and $M^{II}_{2}TiO_5$. Calcium titanate, $CaTiO_3$, occurs in nature as perovskite. The compound Li_2TiO_3 is not a titanate, but is a double oxide with the rock salt structure.

The more commonly occurring mineral ilmenite, iron(II) titanate, $FeTiO_3$, usually contains more iron than is required by this formula. It is isomorphous with hematite, Fe_2O_3; in consequence hematite ores often contain considerable amounts of titanium dioxide. The crystal structure of ilmenite is derived from that of corundum, with which hematite is isomorphous, in such a way that the aluminum atoms are replaced alternately by titanium and iron atoms. The metatitanates of Co^{II}, Ni^{II}, Mn^{II}, Cd, and Mg likewise crystallize with the ilmenite structure, whereas $CaTiO_3$, $SrTiO_3$, and $BaTiO_3$ crystallize in the perovskite structure. The compound Fe_2TiO_5 occurs in nature as pseudobrookite. Titanates of general formula $M^{II}TiO_4$ for which the structures are known (M^{II} = Mg, Zn, Mn, Co), crystallize with the spinel structure.

Titanite or sphene, a monoclinic mineral of the composition $CaO \cdot TiO_2 \cdot SiO_2$, is best represented by the formula $Ca(Ti^{IV}, Fe^{III})(O, OH)[SiO_4]$. X-ray structure analysis has shown that titanite is a silicate.

Peroxytitanic Acid and Peroxytitanates. Titanium salts in neutral or acid solution are colored an intense orange red by hydrogen peroxide. From sufficiently concentrated solutions, peroxytitanic acid, H_4TiO_5, can be precipitated by ammonia as a brownish yellow precipitate. Like titanic acid, peroxytitanic acid forms a gel with a variable water content. The compound contains one peroxy group. It was shown to be a true peroxyacid, and not an H_2O_2 addition product. Peroxytitanyl ions are formed when any dilute, strongly acidified titanium or titanyl salt solutions are treated with hydrogen peroxide. This is used for the analytical detection of titanium.

Titanium Sulfides. Titanium disulfide, TiS_2, is formed by passing a mixture of titanium tetrachloride and hydrogen sulfide through a red-hot porcelain tube:

$$TiCl_4 + 2\,H_2S \rightarrow TiS_2 + 4\,HCl$$

A different reaction takes place between titanium tetrachloride and hydrogen sulfide in the cold, since the latter then acts as a reducing agent, according to:

$$TiCl_4 + H_2S \rightarrow TiCl_2 + 2\,HCl + S$$

Titanium disulfide forms brassy yellow scales with a metallic luster. It is stable in air at normal temperature. When heated it is converted into TiO_2, and on heating in a stream of hydrogen or of nitrogen it yields the lower sulfides Ti_2S_3 and TiS. It is not decomposed by water even on boiling and is also stable towards dilute sulfuric acid, hydrochloric acid, and ammonia. It is decomposed by nitric acid, as well as by hot concentrated sulfuric acid, with the deposition of sulfur. The disulfide is dissolved by boiling caustic potash, with the formation of potassium titanate and potassium sulfide.

14.4. Interstitial Compounds

If titanium compounds are reduced at high temperature in the presence of nitrogen, *titanium nitride* is readily formed in an impure state. Pure titanium nitride TiN is obtainable in the form of a bronze colored powder by strongly heating titanium tetrachloride in a current of ammonia:

$$3\,TiCl_4 + 16\,NH_3 \rightarrow 3\,TiN + {}^{1}/_{2}N_2 + 12\,NH_4Cl$$

It has a structure of the rock salt type.

Titanium can take considerable amounts of boron into solid solution. It also forms two borides TiB (cubic) crystallizes with the zinc blende structure, and TiB_2 (hexagonal) is isotypic with AlB_2, TiB_2 is harder than any other known metallic boride. It is prepared industrially from boron carbide, B_4C, which is manufactured on a considerable scale as an abrasive. This is mixed with B_2O_3, and treated with metallic Ti:

$$7\,Ti + 3\,B_4C + B_2O_3 \rightarrow 7\,TiB_2 + 3\,CO$$

15. Toxicology and Occupational Health

Ti metal generally shows relatively low toxicity as compared to most other heavy metals. The toxicity of its compounds varies to a large extent, being dependent on their physicochemical properties (e.g., water solubility) and chemical reactivity. Ti apparently is not an essential element for humans [161].

The most important compound of Ti industrially is titanium dioxide, TiO_2. $TiCl_4$ is a starting material for other Ti compounds.

In medicine, Ti metal is used in surgical implants and is mostly tolerated by tissue. Other Ti compounds, such as the dioxide, salicylate, and tannate, are widely used in pharmaceutical and cosmetic products. They have been reported to show practically no adverse effects. Ionic cyclopentadienyltitanium(IV) derivatives (titanocene complexes), a new type of antitumor agent, have shown antitumor activities against certain experimental animal tumors [162, 163].

Intoxications with Ti and its compounds are comparatively rare; they occur almost exclusively by occupational exposure.

Biochemistry, toxicokinetics, human and animal toxicity, levels of tolerance, evaluation of health risks to humans, and ecotoxicity of Ti and its compounds have been reviewed [161, 164].

Toxicokinetics. The average intake of TiO_2 in humans is 0.3 – 0.5 mg/d. Approximately the same amount is excreted daily: at least 0.29 mg/d via the feces and 0.01 mg/d via the urine [161, 165, 166]. The rate of gastrointestinal absorption is about 3 % of the ingested material, i.e., most of the ingested Ti is excreted unabsorbed. The mean Ti concentration in blood is 0.07 mg/L [167].

The lungs and the lymph nodes are the predominant target organs for the accumulation of TiO_2 [167, 168]. About 0.4 µg Ti is stored in the lungs per day. In experimental studies in rats, after a single exposure to TiO_2, 40 – 45 % of the deposited material is removed by pulmonary clearance after 25 d. Storage of Ti in the lung is a dose-dependent process [169].

The biological half-life of Ti is between 320 and 640 d. Excretion by other routes than via urine is unknown [161].

Acute Toxicity. Generally TiO_2 behaves as an inert substance which is practically free of acute toxicity. After short-term exposure of guinea pigs to TiO_2 aerosols, an inflammatory response could not be detected; the number of leukocytes and macrophages did not change [170]. In addition, TiO_2 did not lead to the production of hydroxyproline by fibroblasts, which indicates a lack of fibrogenicity [171].

In contrast, $TiCl_4$ represents a considerable toxic hazard to humans [172]. Contact with the skin, the mucous membranes, and the conjunctiva leads to severe irritation and necrosis due to the hydrochloric acid formed by immediate hydrolysis. Contact with the eyes can cause blindness. The vapor leads to lacrymation and to irritation of the lower respiratory tract, with the danger of lung edema. In animal experiments the development of lung edema was more rapid and the death rate after exposure to $TiCl_4$ was higher than with an equivalent concentration of HCl alone, since HCl adsorbed on the particles of hydrolyzed $TiCl_4$ is transported to deeper parts of the respiratory tract which usually are not reached by the highly water soluble HCl [173].

Chronic Toxicity. In a long-term study of up to 390 d with various species, but very low numbers of test animals (two guinea pigs, two rabbits, four cats, one dog), the animals received between 0.6 and 9 g technical grade TiO_2 per day. There were no adverse effects and no histological abnormalities in any of these animals [174]. In a long-term study with mice from weaning to natural death, the addition of 5 mg of titanium potassium oxalate per liter of drinking water led to a decrease of the survival rate after 18 months, which was slight in female mice and more pronounced in male mice [175]. The titanium-fed mice generally showed a higher body weight.

Inhalation of TiO_2 dust by rats for a period of up to 13 months (4 times per day, 5 d per week), followed by a 7-month period of fresh air, did not lead to any pathological effect on the lungs; the weight of the rats remained unchanged [176]. In another inhalation study (10 – 250 mg/m^3 for 6 h/d, 5 d/week) performed for 2 years with rats, exposed groups showed an increase in the incidence of pneumonia, tracheitis, and rhinitis with squamous metaplasia of the anterior nasal cavity.

Rats exposed to 50 and 250 mg/m^3 showed various signs of disturbance of respiratory tract function and dust deposition in the tracheobronchial lymph nodes [177] (see also "Genotoxicity"). These findings were confirmed in detail by an analogous study in which an accumulation of TiO_2 was observed in the upper respiratory tract, lungs, gastrointestinal tract, lymphatic system, liver, and spleen [178].

Similar results concerning effects on respiratory tract function were obtained in a long-term study with rats exposed to $TiCl_4$ (0 – 10 mg/m^3, 6 h/d, 5 d/week) for two years [179].

Ti compounds such as the hydride, carbide, and boride as well as potassium octatitanate and titanium phosphate fibers apparently are fibrinogenic in animal tests [161].

In humans, the most pronounced effects of a chronic occupational TiO_2 exposure appear in the respiratory system [decreased FEV 1 (Forced Expiration Volume during the first second) and FVC (Forced Vital Capacity)], resulting from deposition of TiO_2 in the lung [180].

A case of TiO_2 pneumoconiosis accompanied by lung cancer and slight fibrosis of the interstitium around bronchioles and vessels has been observed with a fifty-three-year-old man who had been employed for about thirteen years with packing of TiO_2 [181].

Genotoxicity. In an inhalation study with TiO_2 dust (10 – 250 mg/m^3 for 6 h/d, 5 d/week) performed for two years with rats, there was an increased incidence of bronchioalveolar adenomas and cystic keratinizing squamous cell carcinomas as well as excessive dust loading in the lung of the 250 mg/m^3 exposure group [177, 178]. These tumors were different from common human lung cancers with respect to tumor type, anatomic location, and tumorigenesis, and were devoid of tumor metastasis [177]. In a ^{32}P postlabeling assay for the detection of DNA adducts, TiO_2 formed one of the two DNA adducts that could be quantitated separately [179]. In contrast, up to 5 % TiO_2 in the diet during 130 weeks did not cause carcinogenic effects in rats [182].

According to the IARC [183], there is inadequate evidence for the carcinogenicity of TiO_2 in humans, and limited evidence for the carcinogenicity of TiO_2 in experimental animals. TiO_2 is not classifiable as to its carcinogenicity to humans (Group 3).

Intratracheal administration of TiO_2 combined with benzo[*a*]pyrene to hamsters causes an increase in the incidence of benign and malignant tumors of the larynx, trachea, and lungs over that in benzo[*a*]pyrene-treated controls.

A two-year inhalation study with rats exposed to $TiCl_4$ (0 – 10 mg/m^3, 6 h/d, 5 d/week) revealed an increased incidence of cystic keratinizing squamous cell carcinomas in high-dose groups [184].

The inhalation of fibrous potassium octatitanate by rats, hamsters, and guinea pigs has basically the same effects on the lungs as asbestos, although the effects are considerably less pronounced [185]. These findings were confirmed by an in-vivo test system [186].

Synthetic titanium phosphate mineral fiber shows a fibrinogenic potential in rats and hamsters after intratracheal injection, similar to that of asbestos; however, in contrast to the results with asbestos, no abnormal increase of the abdominal tumor rate after intraperitoneal injection of 2 – 10 mg/kg was observed [187].

Reproductive Toxicity. In a three-generation study with rats, the addition of titanium potassium oxalate to the drinking water (5 mg/L) led to a marked decrease in the number of animals surviving to the third generation [161]. In pregnant mice, the application of 30 or 60 mg/kg of the antitumor agent titanocene dichloride on day 10 and 12 resulted in the appearance of cleft palate in numerous fetuses and of costal malformations in some fetuses [188].

Immunotoxicity. In a group of dermatitis patients, no evidence of a skin sensitizing potential of TiO_2 could be observed [189].

Toxicological Data. Titanium dioxide, TiO_2: TDLo (rat, intramuscular) 360 mg/kg [190]; titanium tetrachloride, $TiCl_4$: LCLo (mouse, 2 h, inhalation) 10 mg/m^3 [191]; LC_{50} (rat, 4 h, inhalation) 460 mg/m^3 [192]; calcium titanate, $CaTiO_3$: LD_{50} (rat, i. p.) 5300 mg/kg; barium titanate, $BaTiO_3$: LD_{50} (rat, i. p.) 3000 mg/kg; lead titanate, $PbTiO_3$: LD_{50} (rat, i. p.) 2000 mg/kg [161]; tetrabutyl titanate: LD_{50} (mouse, i. v.) 180 mg/kg [193]; dicyclopentadienyltitanium: LDLo (rat, intramuscular) 50 mg/kg, LDLo (hamster, intramuscular) 83 mg/kg [190].

Treatment. After contact of the skin with $TiCl_4$ immediate dry removal (without use of water) is necessary. Thereafter, remaining traces of $TiCl_4$ should be removed with soap and plenty of water. After contact of the eyes with $TiCl_4$, adequate measures are rinsing with plenty of water, use of Isogutt eye drops, and contacting an ophthalmologist as soon as possible. In cases of $TiCl_4$ vapor inhalation, cortisone preparations should be applied immediately (e.g., inhalation of Auxiloson) to avoid the development of lung edema. In severe cases clinical observation for at least 24 h is necessary.

Occupational Health. The MAK value is 6 mg TiO_2/m^3, measured as total fine dust [194]. In the United States the ACGIH set a TLV value of 10 – 20 mg TiO_2/m^3 in 1980 [195].

Lung fibrosis caused by titanium and some of its compounds (carbide, hydride) is included in the list of the German Berufskrankheitenverordnung (Occupational Disease Regulations) [196].

Since TiO_2 tends to accumulate, persons heavily exposed at the workplace should undergo periodical medical examinations, including chest X-rays and ventilatory function tests.

1. History

Tobacco is the most important economic crop that grew up with colonial America. It also helped America grow! On 11 October 1492, when Columbus landed in the New World, he was offered dried tobacco leaves at the House of the Arawaks. The chronology of early tobacco distribution can be summarized as follows. (see below)

Various names were given to the plant, including *Nicotiana*, after Jean Nicot, French Ambassador at Lisbon. Nicot was one of the first to grow tobacco in Portugal, and was largely responsible for making the plant known at the royal court in Paris; the Duc de Guise proposed the name *Nicotiana* in 1585. However, the name tobacco had become established in North America and became the common name. Tobacco grown in France and Spain was *Nicotiana tabacum*, from seed originating in Brazil and Mexico. The species first grown in Portugal and England was *N. rustica* – the seed grown in Portugal came from Florida, while that grown in England came from Virginia.

Tobacco played an important role in farm economics and international trade. In the early 1600s when tobacco was commercially culti-

vated in Virginia, shipping of tobacco leaf helped the development of England's merchant marine, and opened up a valuable export. The Anglo-American tobacco colonies continued to supply the expanding tobacco market throughout the colonial period. In America, from the small beginning at Jamestown, tobacco production in Virginia and Maryland increased rapidly, for it was about the only commodity the colonists could exchange for manufactured products from Europe. Tobacco served to underwrite credit during the Revolutionary War. Independence saw the extension of tobacco growing into North Carolina, Kentucky, Tennessee, Ohio, Missouri, and later into several other States.

Date	Event
1492	(11 October) Columbus offered "dried tobacco leaves" by the Arawaks
1499	Amerigo Vespucci reported the use of chewing tobacco in an island off Venezuela
1545	Iroquois Indians near Montreal, Canada, found to be smoking tobacco
1550	Tobacco pipes later unearthed in China identified as made at this time
1556	Tobacco first grown (or became known) in France
1558	Tobacco in Brazil, Portugal
1559	Tobacco in Spain
1560	*N. rustica* in central Africa
1565	Tobacco in England
1600	Tobacco introduced to Italy, Germany, Norway, Sweden, Russia, Persia, India, Indochina, Japan, China, and west coast of Africa
1612	John Rolfe known to be the first man to grow tobacco for export, at Jamestown, Virginia
1631	Tobacco production extended to Maryland; gradual spread to other areas
1650s	Portuguese took tobacco to South Africa and other countries
	Spanish distributed tobacco to Philippines, Guatemala, and other parts of Central and South America and the West Indies
	Indonesia began tobacco cultivation
	Other European countries began tobacco cultivation
1700s	Tobacco produced in New Zealand
	N. tabacum introduced to Australia (*N. suaveolens* grown prior to this)

2. Botany

2.1. Taxonomy

Commercial tobacco *Nicotiana tabacum* is one of more than 64 known species in the genus. Classification is as follows:

Kingdom:	Plant
Subkingdom:	Embryophyta
Division:	Tracheophyta
Subdivision:	Pteropsida
Class:	Angiospermae
Subclass:	Dicotyledonae
Order:	Solanales
Family:	Solanaceae
Genus:	*Nicotiana*
Species:	*tabacum*

2.2. Nicotiana Species

Nicotiana is classified into subgenera, sections, and species (Table 1). Among those species, 45 are indigenous to North or South America, and 15 to Australia; 5 more species were subsequently identified with some revisions and further changes.

2.3. Tobacco Plant Characteristics

Tobacco is an annual plant, although it is potentially perennial in habit. Among different species, there are variations in leaf shape, size, form of leaf tip, petiolate or sessile, leaf angle to stem, and leaf asymmetry. Leaves of *N. tabacum* are generally ovate or oblong-lancolate and borne directly (sessile) on the main stem; those of *N. rustica* are usually petiolate and of regular ovate or cordate shape.

One of the outstanding characteristics of tobacco is the enormous leaf area it produces. Most varieties have a relatively large leaf and, under favorable conditions the fully mature leaf averages $0.1-0.15\,m^2$ in area. In cigar tobacco, a single plant with 18 leaves may produce $>2\,m^2$ of leaf. In American varieties the leaf does not have a bare petiole. These varieties produce a large, thick stem, the lower portion of which is woody. The flowers are about 1 cm long, and most domestic varieties are pale pink, although some varieties produce white or carmine blossoms. The flower is borne on a short stem and has a five-cleft calyx, from which emerges the slender corolla tube. The latter is much longer than the calyx, and usually expands at the top into a five-lobed stigma. The five stamens are attached to the corolla tube, and each consists of a long, slender filament and an oval anther that splits lengthwise in discharging its pollen. The

pistil is composed of a swollen basal element, the ovary, containing the ovules arranged on a fleshy placenta, a long slender style arising above the ovary, and a more or less two-lobed stigma. The structure of the flower favors self-fertilization.

In the leaf axils there are buds that ordinarily remain dormant during growth, but if the terminal bud is removed these axillary buds readily develop into large branches, "suckers". The plant possesses an extensive, but comparatively shallow system of fibrous roots that usually afford adequate support, though the plant may be toppled by strong winds, especially if it bears a full-size flower head. The growing leaf has a vivid green to blue-green color that varies considerably with the variety and state of nutrition. The color tends to change to yellow-green as the leaf approaches maturity.

3. Genetics and Propagation

3.1. Origin of Tobacco

The origin of *N. tabacum* has been a challenging problem for plant scientists. One hypothesis is that *N. tabacum* comes from an interspecific hybrid between *N. sylvestris* and *N. tomentosa*; another hypothesis is between *N. sylvestris* and *N. tomentosiformis*; a third between *N. sylvestris* and *N. otophora*. The basic concept is that *N. tabacum* (N = 24) is a result of hybridization between two species (N = 12) after chromosome doubling. Many experimental crosses have been conducted to examine such hypotheses on taxonomic and morphological grounds.

Tobacco fraction 1 protein is a unique genetic marker. Synthesis of this photosynthetic enzyme is regulated by both the nuclear and chloroplast genomes. Fraction 1 protein is identical to ribulose-1,5-diphosphate (RuDP) carboxylase – oxygenase, and is constructed from eight large and eight small subunits (L_8S_8). By electrofocusing fraction 1 protein isolated from *N. tabacum* and the putative progenitor species, it has been confirmed that *N. tabacum* arose from the hybridization of *N. sylvestris* females with *N. tomentosiformis* males [1, pp. 195 – 196]. Comparison with the polypeptide compositions of fraction 1 proteins from the three species indicates that *N. sylvestris* contributed the large subunit polypeptides, and therefore was the maternal parent in the original hybridization. *Nicotiana sylvestris* also contributed one of the two small subunit polypeptides of *N. tabacum*. The other polypeptide was contributed by *N. tomentosiformis*. Such evidence proved that the original hybridization was *N. sylvestris* females with *N. tomentosiformis* males, and that *N. otophora* was not involved in the origin of *N. tabacum*.

3.2. Monosomics and Their Characteristics

A plant with variations in its number of whole chromosomes is known as aneuploid. For example, $2n - 1$ is a monosomic and $2n + 1$ is a trisomic. *N. tabacum* has available a complete set of monosomic types and each type has been identified for its distinguishing characteristics.

The monosomics are therefore of special importance because they are the optimum material for locating genes on a specific chromosome. In addition, it is of great value to examine the transfer of single chromosomes between genus, species, or varieties.

3.3. Intraspecific and Interspecific Hybridization

Intraspecific hybridization is a cross between plants within the same species regardless of genetic differences among the parents or the resulting level of heterozygosity of the hybrid.

Through hybridization and other genetic manipulations, desirable characteristics can be incorporated into tobacco plants for cultivation. Intraspecific hybrids generally occur in Mendelian behavior, and interspecific hybrids essentially occur in a non-Mendelian manner. This is because hybrids between plants of the same species have complete chromosome homology, and hybrids between plants of different species have only partial or nonchromosome homology. There are three conventional approaches to interspecific hybridization for the purpose of alien transfer and incorporation of germplasm into stable diploid lines.

1) Diploid × diploid, then doubling to produce the allopolyploid and backcrossing to produce the sesquidiploid
2) Autotetraploid × autotetraploid to produce the allopolyploid directly
3) Autotetraploid × diploid to produce the sesquidiploid directly

Incorporation of alien chromosomes or segments is generally known as introgression. Interspecific hybridization and introgression in natural populations is a known source of genetic variation and adaptation. The goal of experimental interspecific hybridization is usually the introgressive transfer of a specific trait from one species into the genome of another. These techniques are widely used in tobacco genetics, both pure and applied.

3.4. Parasexual Hybridization

Parasexual hybridization was first conducted with tobacco. It is a means of developing hybrid plants by fusion of protoplasts from different species or related plants differing in their cytoplasms. It may also include inserting organelles such as nuclei, plastids, mitochondria, and chromosomes into protoplasts, or inserting microorganisms, including viruses into protoplasts, or transferring nucleic acids or genes into plant cells. Some experimental fusion has also been reported between plants and animals.

Cellular compatibility or incompatibility between species is usually a main factor in deciding the success or failure of the formation of sexual hybrids. Protoplast fusion, however, involves many other conditions; e.g., protoplast fusion and organelle uptake requires the aggregation or agglutination of cells or organelles with cells. Environmental conditions, media formulation, identification and recovery of fused cells, and availability of biochemical or physiological markers are among the many factors requiring more study.

3.5. Techniques for Plant Propagation

This discussion centers on unconventional techniques, which are generally used not for commercial tobacco production, but for plant improvement through novel approaches in varietal development, academic studies in plant science, and development of new technology, using *Nicotiana* plants as experimental material.

Plant Part Culture. Plant part culture is generally known as organ culture. Culture from vegetative organs includes root, shoot apex, stem, and leaf. Reproductive organs include embryo, ovary, and flower bud. In each system, there are requirements for clean or sterilized material, suitable media, adequate nutrient supply, and environmental conditions.

Tissue Culture. *Nicotiana* plant materials are used widely as models for tissue culture. Early tissue culture work was conducted with interspecific *Nicotiana* hybrids, *N. glauca* × *N. langsdorffii*. Tissue or cell cultures have been valuable tools for evaluating growth regulators, organic metabolism, environmental pollutants, disease resistance, chemical

constituents, genetics, and breeding for crop improvement. Different media have been developed for specific tissue. Pith tissues or young stems are commonly used to initiate tissue growth. Subcultures can be generated from the initial callus. There is wide application of tissue culture for disease resistance.

A fundamentally new possibility has been demonstrated for the polyploidization of tobacco diploids and the diploidization of haploids, with the help of tissue culture.

Cell Culture. Cell culture is a phase of tissue culture, but is discussed separately so that more attention can be devoted to individual cells.

Individual tobacco cells have been used for selection of NaCl-tolerant lines. Cell culture may provide a rapid method for producing salt-tolerant crop plants. Both mutagen-treated and untreated cultures develop salt tolerance. The occurrence of spontaneous or induced variants in somatic cell cultures could provide a source of many agriculturally desirable phenotypes.

Anther Culture. Anther-derived haploids are potentially useful in plant physiology and breeding programs. Haploid plants of *N. tabacum* have been obtained by culturing anthers at the microspore stage. Explants of pith tissue from haploid as well as diploid plants have been grown in vitro, and changes in cell number, cell size, and fresh weight determined. Anther culture is also used for research on sterile hybrids and mutants.

4. Production

Tobacco is consumed throughout the world in various forms: smoking, chewing, and snuff. Production occurs in all locations where the environment is suitable.

4.1. General Classification and Environmental Requirements

Classification of leaf tobacco is primarily based on curing methods and tobacco types. The United States system uses tobacco types as broad units, which are broken down into classes. These are further divided into grades determined by quality, size, condition, color, etc. There are many other types of tobacco which differ from the United States classification. Turkish or Oriental tobaccos are mainly "sun" cured. The Maryland tobacco produced in Switzerland is a combination of air and flue curing.

Leaf property, expressed in chemical and physical properties, is very sensitive to environmental factors. Climate and weather have significant effects on leaf type, grade, and quality. Tobacco is of tropical origin and grows most rapidly in a warm climate. However, it is grown as far north as central Sweden, and as far south as southern Australia. The most important temperature factor in determining latitudinal distribution of tobacco production is duration of the frost-free period. In cool climates, ordinary tobacco requires ca. 100 – 120 d from date of transplanting to attain full maturity, at a mean temperature of 27 °C (80°F). In the United States, the length of the growing season, as measured by average dates of the latest killing frost in Spring and the earliest killing frost in the Fall, is >160 d.

Tobacco needs a liberal, well-distributed rainfall to maintain adequate water supply for rapid growth and large size. Prolonged severe drought results in pronounced stunting of the plants and "firing" of the lower leaves. Moderate drought may not materially reduce yield. Relatively wet seasons tend to reduce the yield by producing thin, light-weight leaf. Excessive rainfall may cause injury to the crop through loss of plant nutrients in light soils and drowning of the plants in heavy soils. Relative humidity has an important effect on loss of moisture by the soil and plant. Strong winds may damage the leaf by bruising or physical destruction.

4.2. Seed and Seedlings

Tobacco seeds are extremely small – ca. 300 000 seeds per ounce (10 000 – 11 000 per gram). Each tobacco plant may produce half an ounce (15 g), ca. 150 000 seeds, sufficient for 100 ft^2 (10 m^2) of seedbed area. Under regular conditions, seeds obtained from one plant may provide enough seedlings for 2 – 5 acres (0.15 –2 ha) of field tobacco. Tobacco plants are grown in a seedbed and later transplanted to the field. The seedbed can be any size or shape convenient for

weeding, applying pesticides, pulling plants, etc. Depending on local conditions and disease problems, seedbeds may be permanent or shifted to a new location each year.

Table 2 shows the approximate seeding rate and area that can be planted from an ounce (30 g) of seed.

Table 2. Seeding rate and field acreage from 1 oz (30 g) of seed

Type	Seed bed area		Field transplants	
	square yards	m^2	acres	ha
Flue-cured	600	500	4 – 5	1.5 – 2
Fire-cured	400	350	4 – 6	1.5 – 2.5
Burley	400	350	3 – 4	1.2 – 1.5
Maryland	300	250	3 – 4	1.2 – 1.5
Dark air-cured	400	350	4 – 6	1.5 – 2.5
Cigar filler	100	85	3 – 4	1.2 – 1.5
Cigar binder	100	85	6 – 8	2.5 – 3
Cigar wrapper	100	85	3 – 4	1.2 – 1.5

4.3. Soil and Fertilizer

Tobacco can be grown in sandy soils to heavy clays, but different types of tobacco require special soil types for optimum leaf quality. Tobacco has an active root system which contributes to the rapid development of an enormous leaf area; adequate soil aeration, water, and nutrient supply are three major requirements.

Table 3 shows several well-known tobacco types and their respective soil types.

Table 3. Major tobacco types and their respective soil types

Tobacco	Soil
Flue-cured	sandy loam to fine sandy loam
Burley	silt loam
Maryland	fine sandy loam
Cigar	
Wrapper	sandy loam
Filler	silt loam
Binder	sandy loam
Dark fire-cured	clay loam, silt loam
Oriental	clay sandy topsoil, and chalky subsoil

The ideal fertilization situation is a fully adequate continuous supply of all essential elements through the growing period, with a rapid decline as the crop approaches maturity. The plants need to maintain an uninterrupted, rapid growth from the time of transplanting to the approach of maturity. Deficiency at any stage may delay plant growth and development, and oversupply of food toward the end of the growing season may prevent normal ripening.

4.4. Pests and Pest Control

Tobacco is subject to many pests. Pests may not only induce direct physical damage, but cause related chemical change. Serious attacks by disease or insects early in plant growth may destroy the whole crop. Efforts to breed disease-resistant plants have been very successful, but tobacco plants resistant to insects are still in an early stage of investigation.

4.4.1. Diseases

The causal organisms of the most common tobacco diseases are described in [1, pp. 136]. Many diseases occur in seedbeds; others occur primarily in the field. In addition to causal organisms and plant varieties, environmental conditions contribute to a large proportion of the occurrence as well as the degree of infection.

4.4.2. Insects

Insect damage similar to that of disease, occurs at various stages of tobacco growth. Among the insects which cause serious damage are budworms, hornworms, flea beetles, aphids, and wireworms. More than 100 species feed on tobacco; 35 of these cause enough damage to require treatment.

The important insects and related pests on tobacco, together with description and type of damage, and chemicals for insect control as described in detail in [1]. The level of pesticide residues on tobacco is always a concern for consumers and the tobacco industry. Regulatory actions have resulted in drastic reduction, if not complete elimination, of certain undesirable materials.

4.5. Harvesting

The metabolic activities in tobacco leaves during growth, maturation and senescense are continuous processes and shift gradually from one stage

to the next. Stage of harvesting and method of harvesting are the critical phases in the production of good quality tobacco. They differ according to tobacco type.

Flue-cured tobacco is ripe when the green leaves begin to fade and become a dull, yellow-green with a cream tip. The ripened leaves are primed in lots of three to five at each priming, beginning at the bottom. Normally, primings are made every 4 – 5 d or at weekly intervals, requiring 4 – 6 weeks to harvest an entire crop.

Fire-Cured Tobacco. When mature, the leaves of fire-cured tobacco are thick and heavy, mottled yellow and green. Maturity is commonly reached 30 – 40 d after topping. Gum accumulates on the leaves in dry weather during the interval between topping and harvest. Its presence improves leaf quality.

Burley Tobacco. The plants usually reach maturity ca. 3 – 4 weeks after topping. At maturity, plants become a lighter shade of green. The entire plant is harvested by cutting the stalk as near the ground as possible to save the lower leaves. The best cigarette grades are usually found among the lower and middle leaves.

As the plants are cut, they are at once speared onto a stick, one end of which is forced into the ground at an angle, often so that it rests on the stubble of a cut plant.

In general, the bottom leaves on burley tend to burn before it is cut. If these leaves are primed off early, they may bring a better price. Usually, only one or two primings are profitable before the stalk is cut.

Maryland tobacco is harvested much like burley. Growers may vary in exact harvesting methods; most burley growers spear immediately after cutting the stalk, but cut Maryland tobacco plants are allowed to wilt before field spearing or removal for barn spearing.

Dark air-cured tobacco is harvested like burley. After the plants are cut, they must be allowed to wilt before they are put in curing barns.

Cigar Filler Tobacco. For cigar filler tobacco, plants are harvested when fully ripe, as indicated by pale green color, mottled appearance, and increased thickness and brittleness of the leaves. The plants are cut off near the ground when the weather is clear and the plants are free from dew. The plants are speared on sticks and allowed to wilt on rocks.

Cigar Binder Tobacco. Plants of cigar binder tobacco are harvested when the middle leaves are ripe, as indicated by a lighter shade of green. At this stage, the lower leaves of the plant tend to be more or less overripe and the top leaves show varying stages of maturity. The stalks of the plants are cut near the ground with a special hatchet, and the plants are laid on the ground to wilt before they are handled.

Cigar Wrapper Tobacco. In harvesting all shade-grown tobacco, the tobacco leaves are primed as they ripen. Usually, the first priming of three or four lowermost leaves is made at the time the flower head forms. Subsequent pickings of three or four leaves are usually made at weekly intervals, progressing up the plant until all usable leaves are picked. The plants are not topped.

Oriental tobacco is always harvested by priming, with three to five leaves being taken at a time. Five or six primings are usually required; each is called a "hand" or "row". The leaves are picked at a stage just before full ripeness, when the color is yellow-green and the leaf angle to the stem has increased nearer to 90°. Leaves are threaded onto string. Generally $1.5 - 2 \times 10^6$ leaves per acre are harvested ($3.5 - 5 \times 10^6$ per hectare), and this requires much hand labor.

4.6. Curing

Curing is a vital process, and can be considered as a starvation phenomenon. The purpose of curing is to produce dried leaf of suitable physical properties and chemical composition. Respiratory losses, involving hydrolysis and oxidative deamination, may lead to 20 % loss in dry matter in stalk curing. Various regimes of ventilation, temperature, and humidity control are employed for different types of tobacco.

4.6.1. Flue Curing

Flue curing was the system used in early curing barns; it has almost disappeared. Oil, gas, or electrical heating systems may be used. A type of barn called a bulk barn has been gaining in popularity. Bulk barns are especially constructed and purchased prebuilt from the manufacturer. Air is circulated by a fan through a system of ducts and plenum chambers, rather than by natural movement.

4.6.2. Air Curing

Air curing gives satisfactory results in dry, warm weather. When tobacco is hung in the barn, water evaporates from the leaves, and the barn becomes saturated with moisture. Evaporation soon stops, unless the moisture is removed from the barn by circulating the air.

Under favorable conditions, curing periods for various air-cured tobaccos are 4 – 8 weeks. The temperature should be maintained, and adequate moisture provided, but not so much as to cause molding. The tobacco is cured if the midrib of the leaf is dry enough to snap when bent between the fingers; the stalks may still be green at this stage.

Other curing methods include open fire, dark air curing, sun curing, etc. They are used to achieve the specific characteristics of each type of tobacco. Details may be found in [1].

4.7. Fermentation and Aging

Freshly cured tobacco leaf is unfit for use because of its pungent and irritating smoke. After fermentation and aging, the leaf delivers mild and aromatic smoke. Aging is generally applied to cigarette tobacco, i.e., a mild state of fermentation, usually carried out in a hogshead in compressed conditions for one or two years, at moisture content 10 – 13 %. The loss of dry weight is ca. 1 – 2 % for flue-cured and 3 – 4 % for air-cured leaves.

Fermentation, or sweating, is usually applied to cigar tobacco. It is characterized by high initial moisture content (may reach 50 %), by heat generation, and by 10 – 20 % loss of dry weight. In addition to the improvement of leaf aroma, there is a change to a uniform, darker color, and a grainy leaf texture. During fermentation, there is evolution of CO_2, ammonia and other nitrogenous compounds, and methyl alcohol; uptake of O_2; change of pH; change in water retention; and improvement of fire-holding capacity.

During fermentation, there is a marked increase in ammonia and almost complete loss of asparagine amide nitrogen. Amide-hydrolyzing enzymes are evidently present which ultimately decompose all the asparagine synthesized in the early phase of curing. During cigar fermentation, there is a larger loss of soluble carbohydrates; a considerable decrease in organic acids, pectins, pentosans, hemicelluloses, essential oils, resins, waxes, and pigments; and a small change in cellulose and lignin. The fate of nicotine during fermentation of cigar tobacco has been widely studied.

Aging of tobacco is much milder than fermentation, although fermented tobacco leaf may continue to “age”. The first aging step for cured cigarette tobacco leaves is to subject them to a redrying process, and to bring them to a low and uniform moisture content (9 – 10 %). During aging, little self-heating (except at the beginning) takes place. Small amounts of carbon dioxide, acetic acid, formic acid, and ammonia are evolved during aging; there is an increase in moisture and a decrease in sugar, total nitrogen, water-soluble nitrogen, amino nitrogen, nicotine, total acids, and pH. It is believed that the aging of flue-cured tobacco is essentially a chemical process, the main reaction being that between sugars and amino compounds, with the formation of melanoidins and carbon dioxide.

5. Tobacco Products

Unlike other agricultural products, tobacco is mostly consumed through combustion, only a small amount being used for snuff or chewing.

The manufacture of tobacco products is a science as well as an art. Each finished product has its specific characteristics. The physical properties and chemical composition of each leaf tobacco differ with variety, location, year, environmental variables, postharvest handling, including curing, storage, and aging, and many other factors. Selection of leaf and blending formula are of the greatest importance. Flavoring

and other additives can only "modify" the natural material to a certain degree; casing with sugar may reduce harshness, fructose is used to neutralize irritancy. Other commonly used materials include liquorice, glycerine, honey, vanilla, rum, tonka beans, coumarin, certain acids, aldehydes, lactones, ketones, esters, essential oils, and hundreds of others. The formula is known only by the manufacturer.

5.1. Cigarettes

There are two distinct stages; leaf processing to arrive at the thoroughly mixed blend of cut rag, followed by the use of this rag to make the cigarette.

Where a blended cigarette is being made, from several tobacco types (e.g., flue-cured, burley, and oriental), and one or more of them may be cased, there are as many leaf processing lines as there are types and differential treatments.

The width of cut affects smoking characteristics and cigarette hardness. The finer it is the more complete the combustion, and the coarser it is, within limits, the more the physical characteristics of the cigarette can be preserved at lower tobacco densities. Very thin tobaccos with relatively poor moisture characteristics, such as burley and Maryland, have a high manufacturing loss if cut too fine. The cut for flue-cured cigarette tobacco is 33 – 37 to the inch (0.770 –0.686 mm). The United States custom is for a coarser cut, in line with the above considerations, at 28 – 32 cuts to the inch (0.907 – 0.794 mm). Cut rag must be dried, cooled, and mixed with the cut rolled stem, and stored in silos or bins prior to being fed to the making machines.

In the United States, much or all of the stem is incorporated in the cigarette as reconstituted sheet. In the United Kingdom and many other countries, it is used as cut rolled stem.

Other Cigarette Components The paper has a profound effect on the yield and composition of smoke. One critical paper characteristic is permeability; its primary physical influence is smoke dilution.

Calcium carbonate is used to influence the permeability. Magnesium carbonate may be added to improve ash color, or titanium oxide if a particularly white ash is required.

Another nontobacco part of the cigarette, which has vital influence on the smoking characteristics, is the filter. It may be made from cellulose acetate fibre or paper. The acetate and paper modify the particulate smoke phase by particle retention, and finely divided carbon modifies the gaseous phase.

5.2. Cigars

A typical cigar is 85 % filler, 10.5 % binder, and 4.5 % wrapper. These proportions refer to the weights of leaf actually performing those functions.

Manufacture is essentially forming the filler into the shape of the cigar, wrapping it in the binder to give a bunch, and then covering the whole with the wrapper.

5.3. Pipe Tobacco

"Smoking tobacco" generally refers to pipe tobacco, a mixture of flue-cured with some sun-, air-, and fire-cured leaf. In the United States, the heavy burley leaf forms either a substantial part or the whole of pipe tobacco blends. Perique and Latakia may be added in small quantities to provide their distinct flavors. United States pipe tobaccos are very heavily cased and many United Kingdom brands are top flavored.

The basic problems of mixing the various blend constituents and correctly conditioning the leaf are similar in principle to those with cigarette tobaccos, although moisture levels are much higher in smoking tobaccos than in cigarettes or cigars. In the United Kingdom, the legal maximum is 32 %; typical product mixtures are 20 – 24 %, flake 22 – 26 %, and plug and bar 28 – 30 %.

5.4. Snuff

Fire-cured and dark air-cured tobaccos are used to make snuff. Leaf destined for snuff has been packed and aged in the normal way, and generally the whole leaf is used, but some may be in strip form. Following heavy reconditioning, the

tobacco is repacked to undergo a severe fermentation. In the United States, the tobacco may be cut into strips 1 – 2 in (2.5 – 5.0 cm) wide, before fermentation. The fermented tobacco is dried completely and ground to a fine powder, which must pass a silk bolting cloth containing up to 96 threads per inch (38 per cm). In the United States, snuff may be either blended with a number of flavorings and scents, or left plain. Thee is a dry powder which is placed between the lower lip and the gum, or a moist form which is placed between the cheek and the gum. These forms of consumption differ from the European habit of inhaling through each nostril in turn.

5.5. Chewing Tobacco

In the United States, the four types of chewing tobacco are, in order of sales, loose leaf (scrap), plug, fine-cut, and twist. The basic ingredients are the dark air-cured tobaccos of Pennsylvania and Wisconsin which used to find outlets as cigar binders and fillers. The leaf is stemmed, cut, or granulated, and then either cased heavily (sweet form), cased lightly (semisweet form), or not cased at all. It has been estimated that a sweet form contains, in each 1 pound (0.45 kg) of product, 0.56 pound (0.25 kg) tobacco materials and 0.44 pound (0.20 kg) flavoring additives and moisture.

In the United Kingdom, chewing tobacco is made only as plug. It is unsweetened and usually made of fire-cured tobacco. The wrapper is a particularly fine, thin, well-textured leaf. The moisture content of manufactured plug is about 30 %.

6. Plant Physiology

6.1. Growth and Development

Morphological development of tobacco plants greatly affects the physical and chemical characteristics of tobacco leaf, and thus its quality and usability. Among the most fascinating things about higher plants are the dynamic changes that occur during the life cycle, i.e., growth and development. The ability to function as an autotroph, and to synthesize large, often complex biomolecules from inorganic ions, H_2O, and CO_2 leads not only to new cells, but to new cells that differentiate into tissues with specific functions, e.g., roots, leaves, or flowers.

Environmental and physiological factors affecting growth and development include carbon dioxide, nutrients, temperature, water, and light. Seed germination is the first step of plant growth. The three distinct stages in germination of tobacco seed are: imbibition of water; cell elongation; and increase in cell number. In a physiological sense, the start of germination depends on the coupling of respiration to growth.

In tobacco plants, yield increases with increased total root number and surface area. Root branching and elongation ratios are greater in plants with early rather than late transplanting; at maturing stage, this is reversed.

Cell division may be controlled by auxins and cytokinins; cell elongation and enlargement may be controlled by auxins and gibberelins; while maturation of cells can be influenced by ethylene.

At tissue level, auxin affects the differentiation of vascular tissues and root initiation, and may stimulate cell division in certain tissues and stimulate cell enlargement. Gibberelins may stimulate flowering and cell elongation. Cytokinins are cell division factors and ethylene stimulates aging of tissues in general and the formation of abscissian layers of aging tissues (leaves and fruit) in particular. Abscisic acid is a growth inhibitor, but more importantly, it adapts tissues to deal with stress imposed by salt and/or water.

Senescence is the phase of plant growth that extends from full maturity to actual death, and is characterized by an accumulation of metabolic products, increase in respiratory rate, and loss in dry matter. Many physiological and biochemical changes are associated with senescence of leaves, including yellowing or decrease in chlorophyll, the decline in proteins, RNA, DNA, and increased activity of hydrolytic enzymes such as amylase, invertase, and peroxidase.

6.2. Primary Nutrition

Mineral nutrition is among the most important factors in producing a high-quality leaf tobacco.

Primary elements include N, P, K, and Ca, of which nitrogen is the most important element for growth and development of the tobacco plant and leaf quality, particularly nitrogenous fractions such as protein, amino acids, or nicotine. Nitrogen moves continuously within a plant. Nitrate is the most effective form. The most critical period at which nitrogen exercises the greatest effect on final leaf area is the time prior to emergence of the leaf from the bud, which includes the period of active cell division. Nicotine content increases with increasing nitrogen rates and decreases with increasing irrigation.

Phosphorus is vital in plant metabolism. It is important for plants to have access to a readily available source of phosphate at an early growth stage. In young tobacco leaves, ca. 30 % of the phosphorus is present as RNA and 7 % as DNA.

Although potassium is essential to tobacco growth, its exact role in the metabolic system is not well defined. Potassium is the principal constituent of ash and is important in certain enzyme systems. Tobacco is known as a "luxury" user of potash.

Calcium is essential to cell wall structure and is one of the principal tobacco ash components, next only to potassium. Generally present in the plant as insoluble salts, calcium is not very mobile. It functions as a general regulator of cell metabolism, and may also prevent injury from an excess of other ions.

6.3. Trace Elements and Heavy Metals

Almost all elements are detected in tobacco, including heavy metals. Some are of very minute quantity, which may originate through contaminated soil; some are of significance to tobacco development and growth, e.g., boron, chlorine, copper, iron, magnesium, manganese, molybdenum, selenium, sodium, sulfur, and zinc. Detailed information can be found in [1–3].

6.4. Nutritional Disorders

A deficiency of any element essential for the normal metabolic processes of tobacco plants results in visible or chemical abnormalities, or both. Table 4 is a key to mineral deficiency symptoms on tobacco.

On the other hand, mineral excess can induce physiological disorder in the tobacco plant. Studies in this area are not as extensive as in deficiency. It is known that excess nitrogen produces dark green leaves, promotes vegetative growth, and delays maturity. Excess phosphorus may reduce yield and thicken the leaves. High potassium delays maturity, but increases the rate of burn. Toxicity of excessive minor elements is more frequently reported.

6.5. Physiological Disorder

Physiological disorder of tobacco plants can be induced by various factors including environmental, genetic, and biochemical abnormalities. These abnormalities disturb the delicate balance of normal metabolism, and thus induce chemical and physical changes, reflected in plant growth or leaf appearance.

Pollutants. Many factors contribute to air pollutants, but the most significant source is from energy conversion. Energy conversion products include water, carbon dioxide, carbon monoxide, sulfur dioxide, sulfuric acid, hydrogen sulfide, nitric oxide, nitrogen dioxide, hydrogen fluoroxide, ethylene, ozone, aldehydes, soot, and hydrocarbons. Other materials such as radioactive materials, and many other organic and inorganic wastes are also present as pollutants.

Tobacco "weather fleck", a physiological disorder of the leaf, is associated with the presence of high levels of ozone. Synergism between ozone and sulfur dioxide has been observed. Tobacco plants which did not show damage symptoms when exposed to low-level individual gases, displayed ozone-type injury when exposed to mixtures of ozone and sulfur dioxide at subthreshold concentrations. A separate study showed that ozone was more injurious than SO_2, but in combination the damaging effect of both pollutants on tobacco plants was increased.

Frenching is a noninfectious physiological disorder of tobacco. It usually appears as a network chlorosis of apical leaves, followed by formation of progressively narrower leaves. In extreme cases, there is no expansion of lamina in

Table 4. Key to mineral deficiency symptoms in tobacco

1. Effects localized on older or lower leaves or more or less general on whole plant	(Group 1)
1.1. Local: occurring as mottling or chlorosis with or without necrotic spotting of lower leaves; little or no drying up of lower leaves	
1.1.1. Lower leaves curved or cupped under with yellowish mottling at tips and margins; necrotic spots at tips and margins	potassium
1.1.2. Lower leaves chlorotic between the principal veins at tips, and margins of a light-green to white color; typically, no necrotic spots	magnesium
1.2. General: also yellowing and drying or "firing" of lower leaves	
1.2.1. Plant light green, lower leaves yellow, drying to light-brown color	nitrogen
1.2.2. Plants dark green, leaves narrow in proportion to length; plants immature	phosphorus
2. Effects localized on terminal growth, consisting of upper and bud leaves	(Group 2)
2.1. Dieback involving the terminal bud, preceded by peculiar distortions and necrosis at the tips or base of young leaves making up the terminal growth	
2.1.1. Young leaves making up the terminal bud first light green, followed by a typical hooking downward at tips, followed by necrosis, so that if later growth takes place, tips and margins of the upper leaves are missing	calcium
2.1.2. Young leaves constricted and light green at base, followed by more or less decomposition at leaf base; if later growth takes place, leaves show a twisted or distorted development; broken leaves show blackening of vascular tissue	boron
2.2. Terminal bud remains alive, chlorosis of upper or bud leaves, with or without necrotic spots, veins light or dark green	
2.2.1. Young leaves with necrotic spots scattered over chlorotic leaf, smallest veins tend to remain green, producing a checkered effect	manganese
2.2.2. Young leaves without necrotic spots, chlorosis does or does not involve veins so as to make them dark or light green in color	
2.2.3. Young leaves with veins of a light-green color or of same shade as intervein tissue; color light green, never white or yellow; lower leaves do not dry up	sulfur
2.2.4. Young leaves chlorotic, principal veins characteristically darker green than tissue between the veins; when veins lose their color, all leaf tissue is white or yellow	iron

younger leaves (strapping) or stalk elongation. A series of studies on tobacco concluded that frenching is caused by an organic toxin produced by *Bacillus cereus* Frankland and Frankland. It is suggested that diffusates from *B. cereus*, and perhaps other soil bacteria, may be the cause of frenching of tobacco in the field. Increased populations of the bacillus have been found in adjacent soil and rhizospheres of frenched plants. Diffusion products of these bacteria and the dead bacteria cause symptoms of frenching in aseptically grown tobacco seedlings.

Genetic Tumors. *Nicotiana* tumors may grow spontaneously on stems, roots, leaves, or flower systems on tumorous F_1 progeny or only part of the tissue. Certain *Nicotiana* hybrids produce teratoid proliferations of a genetic origin. The species involved in the production of tumorous interspecific *Nicotiana* hybrids can be separated into two groups – the plus group and the minus group. Hybrids among plus species or hybrids among minus species are free from tumors.

Wounding of leaves of the tobacco hybrid *Nicotiana glauca*×*N. langsdorffii* caused tumor formation at the site of the wound where metabolites would have collected under normal transport conditions.

7. Biochemistry

7.1. Alkaloids

General Concepts. In *Nicotiana* plants, most alkaloids are 3-pyridyl derivatives. Indole alkaloids, such as harmane and norharmane, are also reported, but in very minute quantities. Among the many alkaloid materials found in *Nicotiana*, nicotine is considered the principal alkaloid in commercial tobaccos, and a report confirmed this in 34 of 65 species [1, pp. 427]. Nornicotine appears to be the main alkaloid in 19 of 65 species of *Nicotiana*, and anabasine is the third most important. In another study on alkaloids of 60 *Nicotiana* species, the kinds and amounts, varying with each species, gave no clear-cut correlation between alkaloid amounts and subgeneric or sectional classification [1, pp. 427].

Many 3-pyridyl alkaloids have been reported in *Nicotiana* plants. In cured leaf, 24 pyridine

derivatives have been separated, including nicotine, nornicotine, anabasine, oxynicotine, myosmine, 3-acetylpyridine, 2,3′-dipyridyl, nicotinamide, anatabine, nicotinic acid, and unidentified pyridine alkaloids or derivatives. Major tobacco alkaloids are shown in Figure 1.

Many explanations have been suggested for the presence of alkaloids in plants:

1) Alkaloids serve as protection against insects and herbivores
2) Alkaloids are detoxification products
3) Alkaloids may serve as reserves
4) Alkaloids may include regulatory substances, such as nicotinic acid
5) Alkaloids are useful to the existence of the plant
6) Alkaloids are waste products of metabolism

Nature and Amount of Alkaloids in Nicotiana Plants. Tobacco types, plant parts, cultural practices, degree of ripening, and fertilizer treatment are among the factors which determine the levels of alkaloids in *Nicotiana* plants. Every step in tobacco production that affects plant metabolism influences the level of alkaloid content to a certain degree.

Tobacco leaves have the highest content of nicotine, roots have less, and stalks have the least. Within a leaf, the tip and outer area usually have higher alkaloid content than the base and inner area, respectively. Alkaloid level increases as plants mature, especially during the period after topping. Marked increase of nicotine generally accompanies increased rate of nitrogen fertilization. Under favorable conditions, *N. rustica* consistently produces more nicotine than commercial *N. tabacum*. When grown on fertile soils under irrigation over a period of years, *N. rustica* can consistently produce 150 lb (68 kg) or more of nicotine per acre (165 kg/ha), approximately double the quantity obtained from ordinary tobacco. In *N. tabacum*, a wide variation exists in alkaloid content among varieties. From a random examination of 152 cultivated varieties, a range of alkaloid content between 0.17 and 4.93 % has been found.

Biosynthesis of Alkaloids. Numerous studies indicate that nicotine is formed in the tobacco root and translocated to the top through xylem; nornicotine is the demethylation product of nicotine in the shoot of a plant; and anabasine can be formed in both root and shoot. However, there is evidence of alkaloid formation at other sites in the tobacco plant, e.g., independent nicotine synthesis in both root and aerial portions. Studies on the biosynthesis of tobacco alkaloids have been widely conducted, starting in the early 1930s, and were most active in 1950–1960. They involved areas such as the source of carbon, nitrogen, and hydrogen; the origin of the pyridine ring, the pyrrolidine ring, the piperidine ring, and the *N*-methyl group; enzyme activities, and the interconversion and degradation of alkaloids. In addition, tobacco-specific *N*-nitrosamines, many of which may be related to health problems, are being intensively examined. All these areas are of specific scientific interest as well as health concern.

7.2. Proteins

Tobacco leaf, like other higher plant leaves, contains two classes of proteins: soluble and insoluble, usually equal in quantity. The best-studied leaf protein is the soluble portion, which can be further divided into two major categories on the basis of molecular size. One having a sedimentation value of 18 *S*, representing a single protein is the fraction 1 protein (F 1 protein), whereas all the remaining smaller (4–6 *S*) soluble proteins combine to form the unfractionated proteins or fraction 2 protein (F 2 protein). Generally, there are equal amounts of F 1 and F 2 proteins in the earlier stages of development. Approaching maturation, this proportion is altered, mainly by degradation of F 1 protein. Although our knowledge of F 1 protein is rather comprehensive, there is little information on F 2 protein.

The soluble F 1 protein is found in all organisms containing chlorophyll a, and is ribulose-1,5-diphosphate (RUBP) carboxylase–oxygenase (rubisco) in higher plants. This enzyme has a dual function in that it catalyzes both the carboxylation and oxygenation of RUBP, i.e., the crucial reactions of both photosynthesis and photorespiration; the ratio of these two processes determines the plant's productivity.

Figure 1. Major tobacco alkaloids and related compounds

The essential amino acid compositions of tobacco F 1 protein, egg protein, and milk proteins are similar.

7.3. Carbohydrates and Organic Acids

Carbohydrates and organic acids are known to affect leaf quality. They are major products of plant metabolism, with carbohydrates being present in the greatest amount of any class of compounds in tobacco leaf. Carbohydrates and organic acids are of equal significance to cultivars, cultural practices, and curing in differentiating major tobacco types. As much as 75 % of all the carbon from CO_2 reduced by the plant enters into polysaccharides. Obviously, because of the CO_2 fixation mechanism all the CO_2 fixed by the tobacco plant is in a carbohydrate for at least a brief time.

The main products of CO_2 fixation are sucrose and starch. Sucrose is the primary carbohydrate transported in tobacco, and starch accumulation in the chloroplast is a temporary storage form.

Fructose and glucose, whether free or combined in sucrose, are equally available for starch synthesis and respiration. The rate of sucrose formation may control the rate of starch formation, and the sucrose-phosphate synthetase may be involved in regulation of partitioning of carbon between sucrose and starch. Saccharide is accumulated in the leaves during maturity and decomposed during curing.

In growing plants, an important sink for carbohydrate from photosynthesis is the polysaccharides of the cell wall. Until a leaf is about two-thirds expanded, virtually all carbon fixed in the leaf remains in the leaf; only in the later

stages of leaf development is sucrose translocated to other sinks of the plant.

Primary cell walls have pectin, hemicellulose, and cellulose fractions. Primary cell wall formation utilizes five sugars – glucose, mannose, galactose, xylose, and arabinose – and five sugar derivatives – glucuronic acid, galacturonic acid, rhamnose, fructose, and methyl esters of galacturonic acid.

Nonstructural carbohydrates are sugars or starch, readily available for metabolic processes for energy production and growth; concentrations of nonstructural carbohydrates are subject to drastic changes during curing. Structural carbohydrates are polymers of monosaccharides, most frequently of glucose, galactose, mannose, arabinose, xylose, galacturonic acid, and glucuronic acid. Structural carbohydrates are outside the normal metabolic pools in the plant, and once formed have a very low turnover, and consequently change very little during curing. Midrib contains more cellulose, with higher polymerization of cellulose than in lamina. Lower grade tobacco appears to have cellulose properties more like those of midrib than higher grade leaf.

Many organic acids are known to be present in leaf tobacco. Among nonvolatile acids in leaf tobacco, the major ones are citric, malic, and oxalic; the minor ones are glycolic, succinic, malonic, fumaric, and pyruvic. Among volatile acids in tobacco, acetic and formic acids are the major ones; the minor ones are propionic, α-furanic, benzoic, α-methylbutyric, β-methylvaleric, and many others.

Salts of nonvolatile organic acids, e.g., potassium, magnesium, and calcium salts of organic acids, are always present. Oxalic acid occurs mainly as the calcium salt which, in burley varieties, has been reported to affect the availability of calcium to plant growth, with apparent calcium deficiency as a result.

From a series of studies on the metabolism of organic acids in tobacco leaves, it is evident that when the acid supplied to the plant is one that is metabolically allied with the acids normally occurring, this acid enters readily into the reactions in the cell, and alters the composition of the leaf. This is true for malic, citric, *d*-isocitric, succinic, fumaric, lactic, and pyruvic acid. The only exception is oxalic acid, which appears to be an inert end product.

7.4. Pigments and Polyphenols

Pigments and polyphenols are among the major components which influence leaf quality and usability. Field leaf color is often considered an indicator of the physiological state of growth, and cured leaf color may reflect market value. Phenolic compounds play an important role in leaf color, quality, and physiological strength of smoke. In recent research, the amount and alteration of the amount of free phenols in the smoke has become more important than polyphenols in the tobacco leaf per se.

In many aspects, pigment and polyphenol content of the plant reflect the genetic makeup, plant growth and development, response to pest infection, physical damage, biochemical changes of postharvest treatments, and thus the leaf acceptability and smoke quality. The "brown pigment" is an example which represents a complex product – mainly pigment, polyphenols, protein, and alkaloids.

The major plant pigments in green tobacco are chlorphyll a, chlorphyll b, lutein, β-carotene, neoxanthin, and violaxanthin. Generally, the chlorophyll content of green leaves is 0.5 – 4 %. The total amount of the yellow pigments, carotene and xanthophyll, is about one-fifth to one-third that of chlorophyll in mature tobacco leaves. Carotene from flue-cured tobacco leaves is composed of a mixture of β-carotene and neo-β-carotene in the proportion of 68 : 32, while xanthophyll contains 50 % lutein, 22 % neoxanthin, and 18 % violaxanthin.

The flue-cured varieties have a higher chlorophyll content than the Turkish varieties, and the Turkish tobaccos contain more chlorophyll than the burley types. Only small differences have been observed in the chlorophyll a : chlorophyll b ratio among varieties, the range being 2.14 – 2.40.

In flue-cured tobacco, chlorophyll degradation accompanies individual leaf senescence, while mature burley plants show a progressive decline in chlorophyll concentration from the top to the bottom. In addition, to chlorophyll a and b, β-carotene, lutein, violaxanthin, and neoxanthin, the leaves of certain tobaccos contain antheraxanthin in some harvests.

During leaf curing, the less mature the leaf, the longer the time required for yellowing.

Losses of yellow pigments and dry matter apparently proceed independently of chlorophyll disappearance.

Chlorophyll decreases sharply in the early states of air curing. Carotenoid content also decreases, but the change is rather gradual and incomplete. Rutin and chlorogenic acid remain substantially unchanged in the yellowing stage and decrease in the stages that follow. Loss of chlorogenic acid is almost complete.

Phenolic compounds in living plants occur almost exclusively as glycosides and esters. Polyphenols and related compounds in tobacco include tannins, coumarins, flavanols, simple phenolic derivatives, anthocyanines, and hydroxylated cyclohexanes.

Caffetannins are the only tannins found in tobacco. Chlorogenic acid, its geometric isomer, and their hydrolytic products, caffeic and quinic acids, are the predominant tannin precursors reported. Among the coumarins, scopoletin and its glycosidic derivatives are most frequently found; among the flavonoids, several flavonols are observed, including the glycosides, rutin, isoquercetin, and kaempferol-3-rhamnoglucoside. The predominant anthocyanine is cyanidin-3-rutinoside in flowers of several *Nicotiana* plants. Many other phenolic and related compounds are also reported in leaf tobacco, including catechol, *p*-coumaric acid, *p*-coumerylquinic acid, esculetin, eugenol, ferulic acid, guaiacol, melilotic acid, phenol, quinic acid, shikimic acid, syringic acid, vanillic acid, and others. Quinic acid is believed to be a normal component of leaf tobacco, and is easily lost during drying, which may be the reason for failure to detect this compound in some studies. Pelargonidine-3-rutinoside and two flavonols, quercetin and kaempferol, have also been found.

There is a greater loss of soluble polyphenols during air curing than during flue curing. Results indicate that the interaction of cultural practices with chlorophyll-deficient genes affects the metabolism of chlorophyll and polyphenols during leaf growth and maturation.

During fire curing and air curing, most of the major polyphenols except scopolin and scopoletin are destroyed. These compounds are usually present in both air- and flue-cured tobaccos. There is a progressive increase in scopoletin during flue curing. It is believed that the extra scopoletin arises through hydrolysis of the glucoside scopolin.

7.5. Other Major Compounds

Fatty compounds, lipids, waxes, phytosterols, and related compounds may contribute to leaf aroma; serve as growth regulators; serve as indicators of plant development and processing; serve as bases for chemotaxonomy; and most important, serve as precursors of polynuclear aromatic hydrocarbons (PAH) of smoke condensate.

All aliphatic carboxylic acids may be classified as fatty acids. Usually, fatty acids with ten or fewer carbons, e.g., butyric, caproic, caprylic, capric, are considered lower fatty acids.

Many long-chain fatty acids are present in tobacco seed and leaf. In the tobacco seed oils, the fatty acids are: 75 % linoleic (18 : 2), 15 % oleic (18 : 1), 7 % palmitic (C_{16}), and 3 % stearic acids (C_{18}). In cured bright leaf tobacco, 16 methyl ester compounds have been determined, including lauric (C_{12}), myristic (C_{14}), palmitic (C_{16}), stearic (C_{18}), oleic (18 : 1), linoleic (18 : 2), and linolenic (18 : 3) acids.

The presence of several lower and fatty alcohols in bright tobacco, including *n*-propanol, *n*-butanol, 1-docosanol, 1-eicosanol, ethanol, 1-heneicosanol, 1-heptadecanol, methanol, 3-methyl-1-pentanol, 1-nonadecanol, 1-octadecanol, and 1-tricosanol has been reported.

The characteristic aroma and taste of flue- or air-cured leaves are from the leaf surface lipid fraction. Both leaves contain almost the same amount of alkanes. Terpenes or their degradation products are the components which contribute to aroma and taste of tobacco.

Hydrocarbons are of special significance because they are related to leaf aroma. Analysis of the normal hydrocarbons isolated from tobacco aroma fraction shows the presence of homologues varying from C_{14} to C_{33}. The major fraction, however, is unsaturated material (neophytadiene) and branched hydrocarbons. Alkanes are the major constituent of epicuticular wax, universally distributed in plants. Tobacco leaves contain 5 – 10 mg alkanes per 100 cm^2, gradually increasing with leaf age. Leaves on the upper stalk contain more alkane than those on the lower stalk.

Tobacco terpenoids appear to be related to the flavor and aroma of the product. In the past, tobacco researchers have referred to terpenoids as compounds of hexane or petroleum-ether extractables.

Terpenoids are derived from a basic 5-carbon, isopentene unit. Some terpenes are vital to plant growth; some appear to be secondary metabolites. Terpenes are classified on the basis of number of carbon atoms: hemiterpenes (C_5), monoterpenes (C_{10}), sesquiterpenes (C_{15}), diterpenes (C_{20}), triterpenes (C_{30}), tetraterpenes (C_{40}), and polyterpenes (C_{50} and greater). A study of the diterpenes of *Nicotiana* has shown that they are synthesized within the trichomes, and excreted on to the leaf surface.

Two major classes of diterpenes have been identified in surface extracts and trichome exudates of *Nicotiana* species and *N. tabacum* cultivars. Compounds of the first class, the labdanoids, have been isolated from aged, sun-cured Turkish tobacco, and identified as diterpene lactones belonging to the group of diterpenes typified by labdanoic acid. The labdanoids have a C_6 sidechain and a perhydronaphthalene ring. In general, the labdanes are produced by Turkish, Oriental, and Greek tobacco and some species of *Nicotiana,* while they are absent from *N. tabacum* cultivars of flue-cured, burley, and Maryland types.

The second major class of diterpenes found in the surface washes and trichomes or trichome exudates are macrocyclic, with 14 carbon atoms in the ring. The first of these diterpenes were isolated from aged burley tobacco. Based on chemical and physiochemical properties, these deterpenes have been shown to be diasteroisomers of 12-isopropyl-1,5,9-trimethyl-4,8,13-cyclotetradecatriene-1,3-diol. The common name duvane was assigned to the parent saturated hydrocarbon.

8. Chemical Characteristics

Chemical composition of leaf tobacco varies with genetic makeup, environmental conditions, and every step of production and handling. Major groups and some compounds reported present in leaf tobacco are listed in the following.(see below)

With improved analytical methods and modern instrumentation, minute quantities of many more compounds are likely to be identified in tobacco. The general list summarizes the information available up to now.

In addition, major components representing the differences among principal tobacco types, such as flue-cured, burley, Maryland, and Turkish are listed in Table 5.

Acids

Acetic	Arachidic
Arachidonic	Auxin and indoleacetic acid
Azelaic	Benzoic
Butyric	$C_{10}-C_{23}^{(saturated)}$
$C_{10}-C_{14}^{(normal)}$	$C_{15}-C_{26}^{(iso,\ anteiso)}$
$C_{16}-C_{18}^{(hydroxy)}$	$C_{22}-C_{25}^{(cyclohexyl)}$
Citric	Crotonic
Decanoic	α-Fluorenecarboxylic
Formic	Fumaric
Furoic	D-Glyceric
Glycolic	Glyoxylic
Heptanoic	α-Hydroxyisocaproic
β-Hydroxyiso-caproic	α-Hydroxy-β-methylvaleric
	Hydroxypyruvic
β-Hydroxy-β-methylvaleric	Isobutyric
	2-Isopropylmalic
α-Hydroxyvaleric	α-Ketoglutaric
Isocaproic	Lauric
Isovaleric	Linolenic
Lactic	Malic
Linoleic	α-Methylbutyric
Maleic	
Malonic	
β-Methylvaleric	Octanoic
Nonanoic	Oxalacetic
Oleic	Palmitic
Oxalic	α-Phenyllactic
Phenylacetic	Propionic
Phenylpyruvic	Stearic
Pyruvic	Terephthalic
Succinic	
Valeric	

Alcohols

Aliphatic	
1-Docosanol	1-Eicosanol
Ethanol	1-Heneicosanol
1-Heptadecanol	Methanol
3-Methyl-1-pentanol	1-Nonadecanol
1-Octadecanol	1-Tricosanol

9. Toxicity

Smoking and public health is a controversial issue which has recently become more intense. Tobacco has been smoked for centuries and used for possibly millennia. The idea that smoke might cause cancer was first proposed in 1795, followed by suggestions 100 years later that chemical or physical effects of tobacco dust might cause lung disease. Not until early this century were case control studies reported, mostly on lung cancer.

Numerous studies were conducted on the association with smoking of four diseases: cancer of the lung, myocardial infarction, peripheral vascular disease, and chronic obstructive lung diseases. However, others maintained that the conclusion that smoking is one of the factors that contribute to these diseases is "more fairly described as presumptive than as proved."

In attempting to review and summarize available knowledge, the International Agency for Research on Cancer (IARC) commissioned a group of 28 invited experts in 1985 in Lyon, France, and completed the monograph *Tobacco Smoking*, as a separate volume of IARC series *Evaluation of the Carcinogenic Risk of Chemicals to Humans* [4]. This volume contains in-depth conclusions and evaluations at that time. More recently, tobacco smoke, including mainstream smoke and "environmental tobacco smoke" (ETS), has been reported to be associated with many other health problems. The US Surgeon General provides an annual report on

various aspects of smoking and health. The vast amount of findings and reports cannot be fully discussed in this limited space; current knowledge on toxicity of compounds reported in tobacco is summarized in Table 6 [5].

10. Economics

Tobacco is the most rewarding economic crop for farmers. Despite the health issue, tobacco is still an expanding industry worldwide; average demand for tobacco leaf maintains a 2 % annual increase. In highly industrialized countries, under recession, high tax, and antismoking pressure, tobacco consumption is decreasing by ca. 2 % each year. However, in the developing world, there are continuous increases, far more than the reductions of developed regions. In Asia, the greatest increase in tobacco production has occurred in China. From the mid-1980s, China showed an annual 12 % growth for several years, and recently still maintained an annual 3 % growth. China is now the leading tobacco producer, cigarette manufacturer, and consumer in the world; its exports in 1992 surpassed $\$400\times10^6$. Thailand and South Korea, have also expanded their tobacco industries significantly; Indonesia, the Philippines, Vietnam, and India have also made efforts toward further progress.

In Africa, Malawi tobacco production has promoted its national economy. Zimbabwe's tobacco is the nation's major export. Many other African countries, such as Kenya, Tanzania, Uganda, and Zambia, are eager to follow.

Croatia, Hungary, Bulgaria, Poland, and Slovakia are making progress in both production and manufacture, with varying degrees of success.

For Oriental tobacco, Turkey and Greece still dominate. Turkey has increased its production steadily in recent years, but Greece appears to face some decline.

Almost every country has tried to grow tobacco because of its high economic return, but only a few can produce good-quality, usable tobacco. The United States produces the best quality tobacco, but faces a decrease in production and export because of high production costs in comparison with Brazil and Zimbabwe. Argentina has also increased tobacco production considerably in recent years with a high production cost. At its peak in the early 1960s, the United States produced 25 % of the world total; in 1992, this was reduced to only 9 %. Even so, the United States is likely to continue to produce tobacco. No other crop can provide the same financial return to farmers. This holds true in many other countries.

11. Utilization of Tobacco Other than Smoking

11.1. In Basic Research

Tobacco has been used as a most important research tool in biological science; it is frequently referred to as the *E. coli* of the plant kingdom. A few significant examples are:

1) Photoperiodism
2) Genetics and breeding, especially in molecular genetics (interspecific hybridization, parasexual hybridization or cell fusion, disease resistance, and insect resistance)
3) Growth regulation
4) Pollutants and pollution effects
5) Viruses (tobacco mosaic virus was the foundation for virus research)
6) Plant nutrition (effects of micro- and macroelements on plant growth and development; specific symptoms for diagnosis of nutrition-related disorders)
7) Photosynthesis and photorespiration
8) Organic metabolism
9) Postharvest physiology
10) Total usage of plant products, including biomass

11.2. Use of Nicotine

Nicotine, long established as an insecticide to destroy scabies and lice on cattle, has also been used to destroy scabies, lice, and ticks on sheep. In recent years, nicotine has been used in the form of tobacco dust for pest control in poultry houses. In field plant production, "black leaf 40" – a 40 % solution of nicotine sulfate – can be used to control aphids.

Table 6. Tumorigenic agents in tobacco and tobacco smoke

Compounds	In processed tobacco, per gram	In mainstream smoke, per cigarette	IARC evaluation of evidence of carcinogenicity [a]	
			In laboratory animals	In humans

[a] No designation indicates that an evaluation by IARC has not been carried out.
[b] The 4th report of the Independent Scientific Committee on Smoking and Health (1988) published values for the 14 leading British cigarettes in 1986 (51.4 % of the market) of 20 – 105 µg per cigarette (mean 59 µg) for formaldehyde and 550 – 1150 µg per cigarette (mean 910 µg) for acetylaldehyde.
[c] PAH = polynuclear aromatic hydrocarbons.
[d] ND = not detected.

In animal studies, nicotine administration decreases body weight or retards the normal body weight increase. Cessation of nicotine is accompanied by marked increases in body weight. Similar to the results of human studies, animals receiving large doses of nicotine decrease their consumption of very sweet foods.

11.3. As a Source of Chemicals

Tobacco contains appreciable quantities of citric and malic acids and unique essential oils. Pectin and the enzyme, pectase, are known to occur, at least in the stems. A considerable quantity of resins, possibly suitable for coatings and plastics, is also present.

Many studies have been conducted to provide new uses for low-grade tobaccos; many usable inorganic and organic constituents, e.g., chlorophyll, furfural, sugars, nitrogen, potassium, nicotine, crude fiber, and organic acids, have been found. Development of a market for tobacco seed oil and its residue might make it profitable to produce seed along with tobacco.

11.4. Food and Feed

A class of compounds which can be removed in the pure state and with relative ease is soluble proteins. The biological efficiency of fraction 1 protein as a mammalian nutrient is very high, and its amino acid breakdown is very similar to human or cow's milk. It is far superior in this respect to soybean protein.

Fraction 2 protein has given indications that its nutrient properties as a human food are only a little below those of fraction 1 protein, and much superior to those of soybean. The insoluble proteins and valuable pigments (e.g., xanthophyll) can also be removed in a subsequent solvent extraction process, but this has yet to receive full attention.

11.5. Dust, Midribs, Stems, and Stalks

Tobacco dust can be used as a dry organic fertilizer. Tobacco stems, stalks, and fines have been used for reconstituted sheets. Many other uses are profitable for stems and stalks: animal feed; bedding in animal sheds for cattle and horses; dropping pits for poultry; cigarette paper; and pulp and paper.

11.6. Biomass

Cellulose can be used as cattle feed, or converted to glucose by acid hydrolysis or by an enzyme. The enzyme method gives the highest yields, and is becoming less expensive. Thus, prospects are good that large quantities of glucose derived from wood may become available. This product could be used as food for humans, as a carbon source for microbial formation of protein, or as a feedstock for fermentation yielding liquid fuels, chemicals, and pharmaceuticals.

12. Outlook

12.1. Tobacco in Plant Science

On the frontiers of science, tobacco maintains and expands its role as a research tool for many reasons:

1) There are abundant resources – more than 65 *Nicotiana* species and thousands of germplasm collections which are available and well documented.
2) There is abundant scientific information – tobacco-production-related studies or basic research with tobacco have generated valuable information, providing the foundation for new research.
3) Tobacco is easy to grow. It has a short growing period, has many characteristic markers, and produces a large quantity of seeds per plant.
4) Tobacco tissue and cell culture techniques are well developed for easy and mass production.
5) Tobacco covers broad areas of science – culture, physiology, biochemistry, chemistry, physics, and medical science.
6) Tobacco is a major economic crop in many parts of the world.

12.2. Tobacco in Biotechnology

Biotechnology or genetic engineering is often used to describe the technology of structuring, or purposely restructuring the genetic composition of a cell or a plant. It may be possible to induce or introduce new variation through biotechnology. One approach is protoplast tissue culture. The regeneration of plants from a single cell has been shown to alter the genetic composition of the plant; this can be used to increase resistance to diseases or insects. Another means of introducing new germplasm is by protoplast fusion.

The employment of soil microorganisms in biotechnology has been described in detail by many authors [1, pp. 654]. The tumor-inducing (Ti) plasmid of the soil microorganism *Agrobacterium tumefaciens* is the agent of crown gall disease in dicotyledonous plants.

The *Agrobacterium tumefaciens*-induced tumor cells also produce a series of unusual metabolites, called opines, which are not found in normal plant cells. Both the genes responsible for hormone-independent growth and for opine biosynthesis are encoded by t-DNA. As a result of infection, t-DNA is integrated into the nuclear genome of the host plant, and its expression is responsible for the peculiar traits of the tumor cells. Mutant Ti plasmids have been developed, allowing complete plants to regenerate from transformed cells. These findings have important implications for genetic engineering, as well as for the use of somaclonal variation techniques in plant breeding. Three major possibilities specific to tobacco include:

1) The use of tobacco cell cultures for the production of valuable drugs
2) The modification of tobacco cultivars through genetic engineering to obtain plants with improved resistance various viral, bacterial, fungal, or nematode pathogens, or with modified contents of aromatics and nitrate, or with improved morphological properties or modified senescence properties
3) The breeding of tobacco for food production

12.3. Stress Research

Environmental and biological stresses cause inhibition of growth and reduction of crop yield and quality. Biochemically, plants, like animals, respond to stress by the synthesis of different proteins that are directly related to the type of stress experienced.

Salinity and Tolerance. Cultivated crops are very sensitive to the presence of high concentrations of salt in the soil. Plants must be able to alleviate the detrimental effects of high external concentrations of salts on enzymatic and other metabolic processes necessary to sustain life. The plants must also overcome the dehydration and toxicity induced by salinity.

In general, synthesis of preexisting proteins is inhibited by high salt concentrations, while new proteins are synthesized in response to stress.

Several new proteins, synthesized in response to altered environment, have been reported as "stress" or "shock" proteins in plants.

Sodium Chloride Stress and Sulfate Stress. Sodium chloride is considered the most common source of salinity in plants. The tolerance limits between crops vary, and tobacco plants are among the least tolerant crop tested; tobacco shoot cultures are more tolerant.

Sulfates are much less active in inducing stress than chlorides, and are taken up at a slower rate; in some instances, the uptake rates are described as one-tenth those of chloride.

Sulfate-tolerant shoots also exhibit the highest percentage rooting, particularly in the presence of sulfates, and produce the most abundant roots.

Water Stress. Leaf initiation is greatly inhibited by water deficit. Rate of leaf initiation in well-watered plants is constant with time, but rapidly reduced by a small water deficit. Cell expansion shows a similar response to water shortage, but cell division is much less sensitive.

Heat Stress. Transferring living cells to an elevated temperature produces stress. At injurious temperatures, tobacco tissues respond by increased electrical resistance, followed by a rapid decrease, and irreversible injury to the tissues, with a strong inhibition of oxygen uptake. The most readily observable response to heat stress in many organisms is the induction of heat-shock proteins.

Investigations of formation of heat-shock proteins at different levels of gene expression, as well as studies to distinguish between heat-shock genes and genes for heat tolerance should lead to breeding programs that can select for heat-shock genes and their regulation.

1. Introduction

In the early industrial era, toluene was produced from aromatic fractions, mostly obtained by the coking of hard coal. The importance of toluene as a raw material increased dramatically during World War I, when it was used extensively for the production of the explosive trinitrotoluene (TNT). Since the quantity of toluene produced from coking plants was not sufficient, it was also obtained by direct distillation from aromatic crude oils from Java and Borneo, and by thermal cracking of other naphtha fractions with a narrow boiling range [1].

Sulfuric acid was initially used for refining crude toluene, leading to serious disposal problems. This process began to be replaced by hydrogen refining from ca. 1950.

During World War II, the demand for toluene rose again as a result of increased demand for high-octane aircraft fuels. Production of sufficient quantities of toluene was achieved by development of the catalytic reforming process, in which naphtha fractions from crude petroleum can be converted to reformate with high aromatic content. To isolate pure toluene from reformate, extraction and extractive distillation processes were developed. Pyrolysis gasoline, another source of toluene, became available as a side product of olefin production by steam cracking from about the mid-1960s.

Since then the development of the chemical uses of toluene has lagged behind the increase in its availability. Its relatively low status in chemicals production is mainly because of its lower economic attractiveness compared to the alternative raw material benzene, e.g., for producing phenol or caprolactam. Consequently, considerable quantities of toluene are converted to benzene by hydrodealkylation. Comparatively small quantities of toluene are used for the production of explosives, pharmaceuticals, dyes, and plastics.

A significant proportion of toluene is not isolated in pure form, but is added to motor fuels as a mixture with other aromatics (reformate or pyrolysis gasoline). Because of its high resistance to knocking, the use of toluene as a motor fuel component is frequently more economic than extraction and subsequent use in chemical processes.

History [2]. Toluene (methylbenzene) was discovered by P. S. Pelletier and P. Walter in 1837, during the preparation of coal gas from pine resin. In 1841, H. Sainte-Claire-Deville described the isolation of toluene by the dry distillation of tolu balsam, a solid resinous material with a vanilla-like odor, extracted from the trunk of *Myroxylon balsamum* Harms var. *genium*, a tall tree found in the high plateaus and mountain ranges of South America. In the extraction

process toluene is formed from benzyl cinnamate (3-phenyl-2-propenoic acid phenylmethyl ester).

C. B. MANSFIELD identified toluene in coal tar in 1849. It had been given the name toluin by J. J. BERZELIUS in 1843; later, J. S. MUSPRATT and A. W. HOFMANN changed the name to toluol. In English, toluene refers to the pure substance, whereas toluol refers to a commercial product, of variable purity.

2. Properties

2.1. Physical Properties

Toluene [*108-88-3*], methylbenzene, C_7H_8, is a colorless, flammable liquid of low viscosity with a benzene-like odor. It is a good solvent for fats, oils, tars, resins, sulfur, phosphorus, iodine, etc. It is completely miscible with most organic solvents, e.g., alcohols, ethers, ketones, phenols, esters, and chlorohydrocarbons. Toluene is only slightly soluble in water, 0.047 g/100 mL at 16 °C. At 15 °C the solubility of water in toluene is also very low: 0.4 g/100 mL [2].

Some physical data are listed in the following [2]:

Molecular mass	92.13
mp	−94.991 °C
bp (100 kPa)	110.625 °C
Critical temperature	320.8 °C
Critical pressure	4.133 MPa
Critical compressibility	0.260
Critical molecular volume	0.32 L/mol

Table 1. Data for binary azeotropes of toluene [3,4]

Component	*bp* at 0.1 MPa, °C		Toluene

Binary and ternary azeotropes of toluene are listed in Tables 1 and 2, respectively. Figure 1 shows the vapor pressure as a function of temperature.

2.2. Chemical Properties

Toluene is similar to benzene in its chemical properties, but the methyl group provides additional reactivity. The aromatic nucleus can be hydrogenated to methylcyclohexane. Oxidizing agents preferably attack the methyl group, giving benzaldehyde and then benzoic acid. The latter can be decarboxylated to phenol (Dow and California Research) or hydrogenated to cyclohexanecarboxylic acid (cf. the Snia-Viscosa ε-caprolactam process [6], → Caprolactam, Chap. 4.3.).

Both the nucleus and the side chain can be chlorinated. Nitration leads to *o*- and *p*-nitrotoluenes, which are separated by freezing, solid–liquid separation, and distillation. Further nitration gives di- and trinitrotoluenes; TNT is used as an explosive (→ Explosives, Chap. 5.2.2.).

Some nitrotoluenes are important organic intermediates, as are the toluidines obtainable from them by reduction (starting materials for dye syntheses and vulcanization accelerators), and the dinitriles derived from dinitrotoluenes, which give toluene diisocyanates (→ Isocyanates, Organic, Chap. 4.3.). The latter are starting materials for polyurethanes.

Alkylation of toluene with propylene gives methylcumene isomers (cymenes). Saponification of the cumene hydroperoxides results in the isomeric cresols and acetone (Sumitomo Chemical [7], → Cresols and Xylenols, Chap. 1.4.3.).

Toluenesulfonic acids and acid chlorides are, like chlorotoluene, starting materials for dyes, pharmaceuticals, and saccharin.

2.3. Properties as a Motor Fuel Component

The usefulness of toluene as a motor fuel component depends on how its properties can be combined with those of the other components. Because of the high resistance to knocking and the comparatively low vapor pressure, toluene is highly valued as a motor fuel component [8,9]. In Table 3 the octane number and the vapor pressure values (Reid vapor pressure) of toluene are compared with the specification requirements for unleaded super gasoline (DIN 51 607/EN 228).

Table 3. Octane numbers and vapor pressures of toluene and motor fuel

	Toluene	Unleaded super (DIN 51 607/EN 228)
Research octane number (RON), pure	110	
Motor octane number (MON), pure	98	
Research octane number (RON), typical blend	124	95
Motor octane number (MON), typical blend	112	85
Reid vapor pressure, kPa	0.8	9 (winter) 7 (summer)

3. Separation, Extraction, and Processing

3.1. Separation

It is possible to synthesize toluene industrially by alkylation of benzene with methanol [10], and by cyclization of *n*-heptane with subsequent aromatization [11,12]. However, for economic reasons toluene is extracted from the raw materials described below. They contain toluene, its homologues, other hydrocarbons, and heteroatomic organic compounds. These raw materials originate from:

Reformates from crude petroleum distillates
Liquid products from the pyrolysis of hydrocarbons (steam cracking)

Liquid products from the gasification or coking (pyrolysis) of coal, lignite, etc.

These product streams with their characteristic compositions and treatments have been described in detail [13–16] (→ Xylenes). An important aspect of the extraction of toluene is the fact that the pyrolysis products (from steam cracking, coking, etc.) must be hydrogenated before pure toluene can be extracted. The unsaturated components are converted to saturated ones and the heteroatoms such as sulfur, nitrogen, and oxygen are removed. In the case of reformates such pretreatment is usually unnecessary.

For the separation of toluene from other components within the same boiling range several methods are available, depending on quality requirements. Fine fractionation is now suitable only for the production of toluene with lower purity, and involves significant losses in fores and tails. Azeotropic distillation uses entrainers, such as methanol [13], to separate toluene from nonaromatics; a nonaromatics – methanol fraction with a lower *bp* than the methanol – toluene azeotrope distills at the column head, while pure toluene is removed from its base. Methanol is recovered from the distillate by washing with water.

For economic reasons, extractive distillation is now used only for the separation of toluene from nonaromatics. Technical grade solvents with higher *bp* than toluene have proved to be suitable extraction agents, e.g., *N*-methylpyrrolidone (Distapex process, Lurgi Öl-Gas-Chemie [14, 17]), and morpholine (Morphylane process, Krupp-Koppers [18]). Extractive distillation essentially involves two distillation columns between which the extraction agent is circulated. The toluene-containing material is charged to the extraction column; the extraction agent is charged to the column head. The extraction agent – toluene mixture leaves the column at the bottom, and is separated into pure toluene and extraction agent in a second recovery column. The product obtained at the distillation head of the extraction column contains the nonaromatic components of the starting material and the extraction agent. This fraction is separated in the recovery column into raffinate (nonaromatics) and extraction agent. The latter is then combined with the main portion of extraction agent from the recovery column, and fed back into the extraction column.

If a toluene fraction is a complex aromatic mixture (e.g., benzene – toluene – xylene = BTX), as most raw materials are, then liquid – liquid extraction is necessary. The solvents which have proved suitable industrially are shown in Table 4.

Table 4. Aromatic extraction processes

Process	Licenser	Solvent
Sulfolan	Shell-UOP	tetrahydrothiophene dioxide
Arosolvan	Lurgi	*N*-methylpyrrolidone
Morphylex	Krupp-Koppers	*N*-formylmorpholine
Formex	Snamprogetti	*N*-formylmorpholine
IFP	IFP	dimethyl sulfoxide
Mofex	Leunawerke	methylformamide

A range of other solvents, ethylene glycol, triethylene glycol, tetraethylene glycol, propylene carbonate, etc., have been proposed, but are no longer economically important.

3.2. Processing

Most of the pure toluene produced is converted to benzene by dealkylation. The catalytic conversion takes place in a hydrogen atmosphere at 550 – 650 °C, 3 – 10 MPa. This process, used by UOP, Air Products (Houdry-Lummus), and BASF, is described in more detail elsewhere (→ Benzene, Chap. 5.3.1.).

Another route is thermal dealkylation, using technologies developed by Atlantic Richfield (HDA process), Gulf (THD process), Mitsubishi Petrochemical (MHC process), and UOP. A somewhat higher temperature is used (600 – 800 °C), with a hydrogen atmosphere. The other features of these process (yield, purity, hydrogen consumption, etc.) are similar to those of the catalytic process (→ Benzene, Chap. 5.3.1.).

Toluene is sometimes used for production of xylenes by transalkylation and disproportionation. In transalkylation, one molecule of benzene and one molecule of xylene are formed from two molecules of toluene. The ratio of *o*- to *m*- to *p*-xylene corresponds to that present at thermal equilibrium. Ethylbenzene is formed in small quantities.

Disproportionation is the typcial reaction when only toluene is used. Transalkylation is

Figure 2. The Tatoray process [2, 19]
a) Reactor; b) Stripper; c) Bleaching clay columns; d) Heater; e) Benzene column; f) Toluene column; g) Xylene column; h) C_9 column

used for additional extraction of xylenes starting from toluene and C_9 aromatics (A_9). Methyl groups are transferred from higher alkylated aromatics to less alkylated ones.

The following technologies have achieved industrial importance:

1) Tatoray (UOP)
2) Xylenes-Plus (Atlantic Richfield)
3) LTD, low-temperature disproportionation (Mobil)

The Tatoray process gives ca. 38 % conversion at each pass. Consequently, after removal of the benzene from the reaction product, a toluene fraction is obtained and recycled, then the xylenes and possibly heavier aromatics are distilled from the Tatoray product (Fig. 2) [2, 19]. Publications from UOP [20] on the MSTDP (Mobil selective toluene disproportionation process) [21, 22] describe the characteristics of the Tatoray process and the integration of the disproportionation – transalkylation into an aromatics complex. The Tatoray process was commissioned in nine industrial plants between 1985 and 1993, and is under construction in a further three units. The MSTDP process was successfully commissioned in three industrial plants between 1989 and 1992.

Development work for the production of xylenes from toluene by alkylation with methanol has continued [23], although the economic environment and the availability of toluene do not justify immediate industrial applications.

4. Integration into Refineries and Petrochemical Complexes

Backward Integration into Refineries. Production of toluene from crude petroleum occurs almost exclusively in major refineries and petrochemical complexes [24]. Because of its great importance for the fuel sector, toluene is either added to the motor fuel pool or is extracted and further processed, the proportions varying according to its current economic value [25]. In addition to the capacity for isolation of toluene, a corresponding hydrodealkylation or disproportionation capacity is often retained, so that there can be a flexible response to changes in demand and price between benzene and toluene. The principle of incorporation of toluene production into the structure of a petrochemical refinery is shown in Figure 3 (see next page).

Removal of toluene from reformates or pyrolysis gasoline reduces the octane number in the motor fuel pool, and can lead to a significant gap in the boiling range of the fuel, as is also the case in benzene and xylene extraction. This is known

Figure 3. Incorporation of toluene production into a petrochemical refinery

as a gap fuel characteristic, and must be compensated for by adding alternative components [26]. Addition of pure toluene to the motor fuel pool reduces the benzene content by dilution, which is often welcome in terms of environmental and specification aspects. The octane number is raised. However, in view of a possible future limitation on the total aromatic content in motor fuel in the United States and possibly also western Europe [27–30], removal of toluene from reformate and pyrolysis gasoline could help meet the new specification requirements for gasoline [31–33].

Forward Integration into Chemical Processes. Toluene can be used as a solvent without further processing. In the area of petrochemistry, conversion processes (hydroalkylation or disproportionation) giving benzene and xylenes are the most important. The large number of further processing routes in the chemical industry involve a far greater extent of conversion. Toluene diisocyanate (TDI), phenol, caprolactam, nitrotoluene, and phthalates are produced in the largest quantities (Fig. 4).

5. Economic Aspects

As in the case of benzene and xylenes, toluene production and extraction is affected by the pricedifferential compared with naphtha (Fig. 5) and by the relationship, in terms of net product, between separation and further processing as a raw material for chemicals production compared with direct use as a motor fuel component, in the form of reformate or pyrolysis gasoline [25, 34]. The first aspect is essentially fixed by the economics of reforming naphtha, the second by the economic situations in the mineral oil and chemical industries.

In the 1980s, in western European refineries with appropriate extraction capacities, about one-third of the toluene produced was left in pyrolysis gasoline and reformate, in spite of the possibilities for extraction, and was added to motor fuel directly in this form. In the near future, no significant change in the production and consumption of toluene is expected (Table 5).

Table 6 lists toluene producers, production capacities, and raw material sources in western Europe. Other important production capacities for toluene are in the United States, the CIS, Japan, and Canada [36–38].

6. Quality Requirements

Quality requirements for toluene depend on the type of further processing. Apart from individual specification agreements between producers and customers, there are also generally accepted quality specifications for toluene, e.g., ASTM, EN, ISO, DIN, BS [39, 40]. In the ASTM

Figure 4. Further processing of toluene

Figure 5. Price difference between toluene and naphtha in western Europe [34]

specifications there is a standard quality (Industrial Grade Toluene, ASTM D 362) and a higher purity quality (Nitration Grade Toluene, ASTM D 841) (Table 7). The German standard is DIN 51 633, comparable to ASTM D 841 (Table 7).

7. Storage, Transport, and Safety

To guarantee safe storage, transfer, and transport of flammable liquids Technical Rules for Flammable Liquids (TRbF) have been drawn up in Germany [41, 42], and are continually updated.

For toluene, the same TRbF numbers apply as for xylenes (→ Xylenes).

Because the flash point lies below 21 °C, toluene is assigned to hazard class A I. On storage and transport, toluene must be labeled as highly flammable and slightly toxic [43]. For transport in Germany, it is assigned to class 3, cipher 3b of the GGVS/GGVE regulations governing the transport of hazardous goods by road

Table 5. Production and consumption of toluene in western Europe (in 10^3 t) [25,35]

and rail [44]. The explosion limits of toluene are 1.27 and 6.75 %.

8. Environmental Aspects and Toxicology

8.1. Environmental Aspects

Leakage of toluene into soil or bodies of water constitutes a serious pollution problem. In Germany, toluene is assigned to WGK 2 [42]. The solubility of toluene in water is very low (0.1 g/L at 20 °C). With a vapor pressure of 2.9 kPa (at 20 °C) toluene evaporates relatively rapidly in air; besides the direct toxicological effects (see Section 8.2) secondary reactions with other air pollutants are also important. The reaction with nitrogen oxides in the presence of sunlight leads to the formation of ozone and smog, and can cause severe ecotoxicological pollution [27,45]. Even though toluene undergoes these types of reaction comparatively slowly, extensive measures are increasingly being taken to reduce vapor emissions, both in solvents (where toluene is being replaced to some extent as a result of other developments, e.g., solvent-free paints), and in the fuel sector (in which the emission of toluene into the atmosphere is being significantly lowered by the installation of corresponding vapor retention systems – activated charcoal canisters in passenger cars or gas displacement devices at gasoline stations, storage depots, and refineries) [46,47]. When toluene is used a a fuel compo-

nent, it affects the composition of exhaust gases [27,48].

8.2. Toxicology

From 1 September 1993, the MAK value for toluene was reduced to 50 ppm (190 mg/m^3) [49, 50]. This corresponds to a halving of the 1992 value. With regard to the effect on pregnancy, a parallel reassignment was made to group C (previously group B). Extensive medical data on the effects of toluene were used for the toxicological evaluation. Results of animal experiments supplement the data.

General Activity Profile. Inhalation of toluene vapor affects the central nervous system, giving rise to symptoms such as headaches, dizziness, or coordination difficulties [51–55]. Loss of consciousness can occur at higher concentration [56]. On acute skin contact with liquid toluene, removal of oils and drying of the skin can occur, with development of dermatitis as a possible consequence. The direct irritant effect of toluene is relatively low [56,57].

Acute and Subacute Toxicity. In animal experiments the following toxicity values were found [58]:

Rat, oral, LD_{50} = 5000 mg/kg
Rabbit, percutaneous, LD_{50} = 12 124 mg/kg
Mouse, 8 h inhalation, LC_{50} = 5320 mg/m^3

On exposure for several hours to <1000 mL/m^3 toluene in inhaled air, no significant effects were established in rats [59]. In the concentration range ca. 2000 mL/m^3, in rats, pulse rate was increased many times and a state of exhaustion was recorded [55]; at higher concentrations, a narcotic effect predominated [60–62].

In humans, concentrations up to ca. 800 mL/m^3 affect the central nervous system, causing confusion, headache, nausea, or coordination difficulties as the most obvious effects [51–55]. Weakness and tiredness are also observed. The effect of toluene on the central nervous system can lead to hallucination and addiction (solvent sniffing). In three cases of death following frequent deliberate inhalation of large quantities of toluene-containing solvents, the lethal dose for humans was estimated as 2000 mL/m^3 within 30 min [63]. At high concentrations, disruption of kidney function is observed [64].

Chronic Toxicity. On prolonged exposure, toluene accumulates in the brain [65]. As with acute intoxication, this leads to damage to the central nervous system. However, in animal experiments this is clearly visible only at concentrations of >500 mL/m^3 [66]. Only at much higher doses were damage to the liver [67] and cardiotoxic effects [68] established in rats and mice. However, in animal experiments, after initial suspicions, there was no confirmation of a

leukemogenic effect similar to that found with benzene.

Many toxic effects which have been recorded for humans with high exposure to solvents cannot be attributed to toluene according to current knowledge, but mainly to small quantities of benzene present as an impurity [69,70]. The effects of acute intoxication on the central nervous system with the symptoms already mentioned are, however, characteristic. Damage to internal organs through chronic inhalation of comparatively low toluene concentrations (up to ca. 200 – 400 mg/m^3) is not unambiguously detectable [71]. However, the chronic inhalation of high doses of toluene (solvent abuse) leads to damage to the cerebellum, disruption of the metabolism, and muscle weakness [72,73].

Pharmacokinetics and Metabolism. In humans, the main route for taking in toluene is by inhalation of vapor. Toluene retention in the lungs on prolonged exposure is ca. 50 %, and can be raised by bodily exertion [74,75]. Half-lives between ca. 2 min and ca. 3.5 s have been reported [76,77]. According to more recent discoveries, the percutaneous resorption rate on skin contact with liquid toluene is 0.17 mg cm^{-2} h^{-1}, considerably lower than assumed previously [78].

The metabolic conversion of toluene mainly occurs in the liver. Degradation takes place over many steps and involves the formation of benzaldehyde and benzoic acid, and their conjugation with glycine to give hippuric acid, which is excreted in the urine. Phenolic metabolites (*o*- and *p*-cresol) have also been detected in the urine in small quantities (up to ca. 0.2 %) [79,80].

Mutagenicity, Teratogenicity, and Carcinogenicity. In the Ames test using *Salmonella typhimurium* strains, no mutagenic effects could be detected with toluene, with or without metabolic activation [81,82].

On testing the effect of toluene on mice, no increase in chromosomal aberrations was established [83]. In a more recent study, in humans exposed to toluene vapor in the concentration range 200 – 300 mL/m^3 for ca. 16 a, significant increase in structural changes was observed (chromatid cleavage and exchange), which could be detected up to two years after exposure had terminated [84]. In a large number of animal experiments, there was no certain evidence for teratogenic effects [85]. No indication of a carcinogenic or cocarcinogenic potential has been found for toluene [86].

1. Introduction

Early commercial production of toluidines involved the nitration of toluene followed by a dissolving metal reduction, usually with iron and hydrochloric acid, to give a mixture of toluidine isomers. These early mixed toluidines were commercially important as dye intermediates. Today the isomers are separated by fractional distillation at the nitrotoluene stage, and the individual compounds typically reduced by catalytic hydrogenation. Current commercial applications for mixed toluidines, and more importantly for the individual toluidine isomers, include their use as: intermediates for dyes and pigments, pesticides, and herbicides; vulcanizing accelerators for the rubber industry; polymer curing agents; corrosion inhibitors; pharmaceutical intermediates; and intermediates for numerous other fine and speciality chemical areas.

2. Physical and Chemical Properties

Table 1 (see next page) provides a list of selected physical properties of the three isomers of toluidine (aminotoluene), C_7H_9N, M_r 107.2.

The chemical properties of the toluidines are greatly influenced by delocalization over the aromatic ring of the two unshared electrons on nitrogen, as well as, to a lesser extent, by the electron-donating inductive effect of the methyl group.

The toluidines are relatively weak bases ($pK_b \approx 9$) when compared to aliphatic amines ($pK_b \approx 2-3$) [1] (→ Amines, Aliphatic). However, toluidines do still display many properties similar to those of aliphatic amines, such as alkylation, acylation, and salt formation with strong acids. The toluidines differ from aliphatic amines in their reaction with nitrous acid, in that they form relatively stable diazonium salts which are in turn very important in the textile-dye industry.

Reactions involving the aromatic ring (e.g., substitution reactions; → Amines, Aromatic) are influenced by the strong ring-activating effect of the amine group, and to a lesser extent that of the methyl group. The amine group is a strong *ortho*–*para* director, and only if the amine group is deactivated by extensive protonation or quaternization does the methyl group exert any significant directing effect.

3. Production

The manufacture of toluidines begins with a mixed-acid (nitric/sulfuric acid) mononitration of toluene, which produces all three isomers (*ortho*, *meta*, and *para*), usually in the ratio 15:1 : 9,

Autoignition temperature, °C	482	482	482

respectively. Since the isomeric toluidines themselves cannot be effectively separated by distillation, distillative separation of the isomers is achieved at the nitrotoluene stage.

The literature describes a multitude of methods for reducing nitrotoluenes to toluidines (→ Amines, Aromatic, Chap. 3.1.; → Aniline, Chap. 3.2.2.,). These range from dissolving-metal reductions, such as the Béchamp process [2,3] of years ago, to catalytic hydrogenation. Currently, high-volume manufacture of toluidines utilizes the same type of continuous vapor-phase hydrogenation process used for aniline manufacture [4] (→ Aniline, Chap. 3.2.1.). The catalysts include various supported metals [5,6], Raney nickel [7,8], copper [4], molybdenum, tungsten, vanadium, and noble metals [9–12]. The catalyst is suspended in a column or bed, and a gaseous mixture of the nitrotoluene and excess hydrogen is passed over it at about 250 °C. The gaseous products are condensed, the aqueous and organic layers are separated, excess hydrogen is recycled, and the final crude product is dried and distilled.

Batch liquid-phase catalytic hydrogenation is a common process for the production of lower-volume specialty toluidines or amines too high in molecular mass or too sensitive for vapor-phase reactions. In these cases, liquid nitro compounds can either be reduced neat or else dissolved in appropriate aromatic solvents, aliphatic alcohols, or esters. Catalysts include Raney nickel and supported noble metals. Reduction is conducted between room temperature and 150 °C under hydrogen pressures in the range 350–3500 kPa.

There are several alternative possibilities for reducing nitrotoluenes to toluidines, utilizing such reducing agents as hydrazine [13], alkaline sulfide [14], and sodium hydrosulfite [15]. These methods rarely find commercial application unless the substrate nitro compound has a functional group that might be adversely affected by catalytic hydrogenation.

Additional manufacturing techniques involve the amination of corresponding phenol derivatives [16,17]. This method has been used commercially to produce *m*-toluidine from *m*-cresol.

4. Quality Specifications, Storage, and Transportation

Typical purity of each of the commercially available toluidine isomers is ca. 99.5 % minimum, with a maximum of 0.5 % total for all other isomers. Moisture is usually in the range 0.1 – 0.2 % maximum [18]. Additional specifications important for specific isomer applications are sometimes stated, such as a 1 °C distillation range for 5 % to 95 % of a distilled *o*-toluidine, or a freezing point minimum of 43.0 °C for *p*-toluidine. Assays and moisture content are usually established by GC analysis.

Toluidines are typically stored in steel tanks or drums. All the toluidine isomers exhibit solvent-like properties, so plastics, wax coatings, or other nonmetallic materials are rarely permitted in the context of storage or handling. Teflon TFE or FEP fluorocarbon resins are the preferred materials for gaskets and packaging. When stored in the presence of air all the toluidine isomers tend to discolor, particularly over an extended period of time.

Toluidines are typically shipped in steel drums, tank trucks, rail tank cars, or marine ves-

sels. For transportation by truck, rail, or ship the applicable hazard classification is UN 1708, RQ.

5. Uses

Since *o*-toluidine is the isomer produced in greatest volume, it has found the most commercial applications. By far the single largest use for *o*-toluidine is in the preparation of 6-ethyl-*o*-toluidine, an intermediate in the manufacture of the two very large-volume herbicides Metolachlor [19] and Acetochlor [20]. Another important use area for *o*-toluidine is rubber chemicals. Thus, *o*-toluidine is used in the manufacture of a rubber antioxidant developed by Goodyear called Wingstay as well as di-*o*-tolylguanidine, a non-staining rubber accelerator (→ Amines, Aromatic, Chap. 2.2.2.; → Guanidine and Derivatives, Chap. 2.4.2.). Acetoacet-*o*-toluidine, 3-hydroxy-2-naphthoyl-*o*-toluidine, 2-toluidine-5-sulfonic acid, and *o*-aminoazotoluene are four of the more important dye and pigment intermediates manufactured from *o*-toluidine. In addition, *o*-toluidine is used to manufacture epoxy resin hardeners such as methylene-bis-2-methylcyclohexylamine [21], fungicide intermediates such as 2-amino-4-methylbenzothiazole [22], and *o*-fluorobenzoyl chloride [23]. Certain pharmaceutical intermediates are also prepared starting with *o*-toluidine [24].

Both *m*- and *p*-toluidines still find considerable application in the dye and pigment industries, as well as in the manufacture of triarylmethane dyes. Two compounds derived from *m*- and *p*-toludine, *N,N*-dimethyl-*m*-toluidine and *N,N*-dimethyl-*p*-toluidine, have found use as accelerators for peroxide-cured epoxy and unsaturated polyester resins [25–27]. *m*-Toluidine is used in the manufacture of three important photographic color developers: color developer 2 uses *N,N*-diethyl-*m*-toluidine as an intermediate, and color developers 3 and 4 are based on *N*-hydroxyethyl-*N*-ethyl-*m*-toluidine. Just as with *o*-toluidine, the *m*- and *p*-toluidines find many applications as starting materials and intermediates in the manufacture of various fine and specialty chemicals [28–30].

6. Derivatives

6.1. *N*-Alkyltoluidines

N-Alkyltoluidines can be prepared from unalkylated toluidines with such common alkylating agents as alkyl halides, sulfates, and carbonates. However, large-scale manufacture of *N*-alkyltoluidines usually involves one of two alternative methods: acid-catalyzed alkylation with lower unbranched alcohols or ethers [31], or reductive alkylation with lower aldehydes or ketones over active-metal catalysts (e.g., nickel, platinum, or palladium) and under hydrogen pressure [32]. Toluidines can also be alkylated with reactive three-membered-ring compounds such as ethylene oxide and aziridine.

Important examples include:

N-Methyl-*o*-toluidine [*611-21-2*], M_r 121.18, *bp* 207 – 208 °C, ϱ 0.97
N-Ethyl-*o*-toluidine [*94-68-8*], M_r 135.21, *bp* 218 – 219 °C, ϱ 0.94
N,N-Dimethyl-*o*-toluidine [*609-72-3*], M_r 135.21, *bp* 221 – 222 °C, ϱ 0.94
N-Methyl-*m*-toluidine, [*696-44-6*], M_r 121.18, *bp* 206 – 207 °C, ϱ 0.95
N-Ethyl-*m*-toluidine [*102-27-2*], M_r 135.21, *bp* 221 °C, ϱ 0.96
N,N-Dimethyl-*m*-toluidine [*121-72-2*], M_r 135.21, *bp* 215 – 216 °C, ϱ 0.93
N-Ethyl-*N*-(2-hydroxyethyl)-*m*-toluidine [*91-88-3*], M_r 179.26, *bp* 114 – 115 °C (0.1 kPa), ϱ 1.02
N-Methyl-*p*-toluidine [*623-08-5*], M_r 121.18, *bp* 208 – 209 °C, ϱ 0.94
N-Ethyl-*p*-toluidine [*622-57-1*], M_r 135.21, *bp* 217 – 218 °C, ϱ 0.95
N,N-Dimethyl-*p*-toluidine [*99-97-8*], M_r 135.21, *bp* 211 – 212 °C, ϱ 0.94

6.2. Chlorotoluidines

There exist four monochlorinated isomers each for *o*- and *m*-toluidine, and two for *p*-toluidine. Some are rather difficult to prepare, and thus do not find commercial application. Chlorotoludines are usually prepared by reducing the nitro group of the corresponding chloronitrotoluene. These reductions have traditionally been

accomplished by dissolving-metal reductions, such as the Béchamp process. Today, catalytic hydrogenation is the method of choice, especially since catalysts with improved selectivity almost eliminate dehydrochlorination side reactions [33,34]. The intermediate chloronitrotoluenes are obtained by either chlorination of nitrotoluenes or nitration of chlorotoluenes. Direct chlorination of toluidines can also be accomplished by first protecting the amine function. Chlorotoluidines find commercial applications in such areas as azo dyes, agricultural chemicals, and pharmaceuticals.

3-Chloro-*o*-toluidine, 3-chloro-2-methylaniline [*87-60-5*] (**1**), M_r 141.6, *mp* 2 °C, *bp* 241 –242 °C, ϱ 1.19, is produced by the catalytic hydrogenation of 3-chloro-6-nitrotoluene [35], which is in turn obtained via the acidic chlorination of *o*-nitrotoluene followed by separation of isomers by distillation. An alternate method of preparing the nitro intermediate involves nitration of *o*-chlorotoluene, which also produces a mixture of isomers that can be separated by distillation. The compound is used in the manufacture of azo dyes, and as an intermediate in the manufacture of 2,6-dichlorotoluene.

4-Chloro-*o*-toluidine, 4-chloro-2-methylaniline [*95-69-2*] (**2**), M_r 141.6, *mp* 29 – 30 °C, *bp* 240 –241 °C, is produced by the direct chlorination of acetyl-protected *o*-toluidine. After removal of the protecting group with base, the 4-chloro-*o*-toluidine is separated by distillation from the 6-chloro-*o*-toluidine isomer, described below. This compound is employed in the manufacture of the pesticide Chlordimeform [36], and for making acid azo dyes. Use of the pesticide is declining because of concern over its carcinogenicity [37,38], and Chlordimeform has in fact been banned in several countries.

5-Chloro-*o*-toluidine, 5-chloro-2-methylaniline [*95-79-4*] (**3**), M_r 141.6, *mp* 20 – 22 °C, *bp* 237 °C, is produced by reduction of the nitro group in 4-chloro-2-nitrotoluene, which is itself prepared by nitration of *p*-chlorotoluene followed by distillatory separation of 4-chloro-2-nitrotoluene from the accompanying 4-chloro-3-nitrotoluene isomer (see below 6-chloro- *m*-toluidine).

1 **2** **3**

6-Chloro-*o*-toluidine, 6-chloro-2-methylaniline [*87-63-8*] (**4**), M_r 141.6, *mp* 8 – 9 °C, *bp* 220 °C, ϱ 1.15, is co-produced along with 4-chloro-*o*-toluidine, as described above, and is used as an intermediate in the manufacture of azo and xanthene dyes [39] as well as pharmaceuticals [40,41].

6-Chloro-*m*-toluidine, 6-chloro-3-methylaniline [*95-81-8*] (**5**), M_r 141.6, *mp* 29 – 30 °C, *bp* 228 – 230 °C, is produced by the nitro reduction of 4-chloro-3-nitrotoluene, where the nitro intermediate is co-produced in the nitration of *p*-chlorotoluene described above under 5-chloro-*o*-toluidine. It is used in the manufacture of azo dyes.

3-Chloro-*p*-toluidine, 3-chloro-4-methylaniline [*95-74-9*] (**6**), M_r 141.6, *mp* 24 – 25 °C, *bp* 237 – 238 °C, is produced by the catalytic hydrogenation [8] of 2-chloro-4-nitrotoluene, obtained in the chlorination of *p*-nitrotoluene. It serves as an intermediate in the manufacture of the herbicide Chlortoluron [42,43] and the red pigment intermediate "2B-Acid."

4 **5** **6**

6.3. Toluidinesulfonic Acids

There are ten distinct toluidinesulfonic acid isomers. Several of the isomers are difficult to prepare, and only five have found commercial use. Toluidinesulfonic acids find application in the manufacture of direct dyes, acid dyes, pigments, and triarylmethane dyes.

The toluidinesulfonic acids are produced either by sulfonation of the appropriate nitrotoluene, or by nitration of a toluenesulfonic acid

followed by catalytic hydrogenation or chemical reduction of the nitro group. Other methods involve direct sulfonation of the appropriate toluidine isomer.

Commercial toluidinesulfonic acids are light yellow to red. Often they are hygroscopic solids without defined melting points. Just as with other amino acids, the toluidinesulfonic acids form zwitterionic inner salts that are sparingly soluble in water and dilute mineral acids, but very soluble in aqueous caustic (→ Amino Acids, Chap. 2.).

3-Amino-4-methylbenzenesulfonic acid, 3-amino-*p*-toluenesulfonic acid [*618-03-1*] (**7**), M_r 187.2, is produced by the low-temperature sulfonation of *o*-nitrotoluene with oleum followed by catalytic hydrogenation or chemical reduction. It is used in the manufacture of azo dyes and nonlinear optical materials [44].

4-Amino-3-methylbenzenesulfonic acid, 4-amino-*m*-toluenesulfonic acid [*98-33-9*] (**8**), M_r 187.2, is produced by the sulfonation of *o*-toluidine. The conditions entail heating at 150 – 200 °C in concentrated sulfuric acid, or heating the *o*-toluidine sulfate salt either neat or in an inert solvent. The compound is used as an intermediate in the manufacture of azo and diazo acid dyes [45], pigments [46], and fluorescent brighteners [47].

4-Amino-2-methylbenzenesulfonic acid, 4-amino-*o*-toluenesulfonic acid [*133-78-8*] (**9**), M_r 187.2, is produced by sulfonation of *m*-nitrotoluene to give 4-nitro-2-methylbenzenesulfonic acid, followed by catalytic hydrogenation or chemical reduction. Much older technology involves baking *m*-toluidine sulfate or heating *m*-toluidine with sulfamic acid. The compound is used in the manufacture of azo dyes.

8

9

5-Amino-2-methylbenzenesulfonic acid, 5-amino-*o*-toluenesulfonic acid [*118-88-7*] (**10**), M_r 187.2, is produced by the sulfonation of *p*-nitrotoluene with oleum or SO_3, followed by catalytic hydrogenation or chemical reduction. It is used as an intermediate in the manufacture of azo and anthraquinone acid dyes.

2-Amino-5-methylbenzenesulfonic acid, 6-amino-*m*-toluenesulfonic acid [*88-44-8*] (**11**), M_r 187.2, is produced by direct sulfonation of *p*-toluidine with either concentrated sulfuric acid at high temperature or various concentrations of oleum [48], or by heating *p*-toluidine sulfate salt neat [49] or in an inert solvent [50]. The compound is better known as 4B Acid, and is used as an intermediate in the manufacture of several azo acid dyes, plastics, and printing-ink pigments (e.g., Pigment Red 57, Lithol Rubine), as well as fluorescent brighteners [51].

10

11

6.4. Chlorotoluidinesulfonic Acids

There are thirty different chlorotoluidinesulfonic acid isomers, only a few of which have commercial applications. The commercial potential of these compounds is determined by the availability of appropriate starting materials and the selectivity of the manufacturing process. Many of the possible isomers are prepared as mixtures containing other isomers, and are unusable as such for most commercial applications. Thus, only reactions that produce essentially one isomer are of significance. Commercial applications center around the manufacture of dyes and pigments for the textile, paint, printing ink, and plastics industries.

Chlorotoluidinesulfonic acids can be produced by a variety of methods depending on the choice of starting materials. Chlorination of nitrotoluenesulfonic acids or sulfonation of chloronitrotoluenes both result in chloronitrotoluenesulfonic acids, which can then be catalytically hydrogenated or chemically reduced to the desired product. Care must be taken in selecting the hydrogenation conditions, because catalytic dehalogenation can become the major reaction path with certain catalysts (e.g., very active platinum or palladium catalysts). Some nickel and

poisoned platinum and palladium catalysts minimize the extent of dehalogenation [33]. Additional manufacturing methods for chlorotoluidinesulfonic acids include the chlorination of toluidinesulfonic acids and the sulfonation of chlorotoluidines.

Chlorotoluidinesulfonic acids also form zwitterionic inner salts, with solubility properties much like those of the toluidinesulfonic acids.

2-Amino-3-chlorotoluene-5-sulfonic acid, 4-amino-3-chloro-5-methylbenzenesulfonic acid [*6387-14-0*] (**12**), M_r 221.7, can be produced by the chlorination of acyl-protected 2-aminotoluene-5-sulfonic acid [52], by baking the sulfate salt of 6-chloro-2-methylaniline, or by sulfonation of 6-chloro-3-methylaniline with oleum. It serves as an intermediate in the manufacture of such azo acid dyes as Direct Red 108, C.I. 28165.

2-Amino-6-chlorotoluene-3-sulfonic acid, 2-amino-4-chloro-3-methylbenzenesulfonic acid [*79380-22-6*] (**13**), M_r 221.7, is produced either by sulfonation of 3-chloro-2-methylaniline with oleum at 70 – 90 °C or by heating the corresponding sulfate salt at 150 – 200 °C, the "baking method" [53]. It is an intermediate in the manufacture of azo dyes.

2-Amino-6-chlorotoluene-4-sulfonic acid, 3-amino-5-chloro-4-methylbenzenesulfonic acid [*6387-27-5*] (**14**), M_r 221.7, is produced by sulfonating 6-chloro-2-nitrotoluene with 20 % oleum to give 6-chloro-2-nitrotoluene-4-sulfonic acid, followed by catalytic hydrogenation [54] or chemical reduction. It is used as the diazo component for a series of acid azo dyes intended primarily for leather dying (e.g., Acid Brown 105, C.I. 33530).

12 **13** **14**

3-Amino-6-chlorotoluene-4-sulfonic acid, 2-amino-5-chloro-4-methylbenzenesulfonic acid [*88-53-9*] (**15**), M_r 221.7, was traditionally prepared by a route that proceeds from *p*-toluenesulfonic acid via sequential chlorination, nitration, isomer separation, and reduction. More recent modifications begin with *m*-toluidine and involve acylation, chlorination, de-acylation, and sulfonation [55]. Yet another route uses *o*-chlorotoluene as starting material and proceeds via nitration, catalytic hydrogenation, and sulfonation of the amine [56]. Thiopolyols have been shown to be effective dehalogenation inhibitors during hydrogenation [57]. The compound is known commercially by several common names (e.g., Red Lake C Amine, Lake Red C Amine, C-Acid), and constitutes the diazo component for various azo dyes, metallized dyes, and pigments intended primarily for printing inks and plastics (e.g., Pigment Red 52, C.I. 15860, and Pigment Red 53, C.I. 15585).

4-Amino-6-chlorotoluene-3-sulfonic acid, 2-amino-4-chloro-5-methylbenzenesulfonic acid [*88-51-7*] (**16**), M_r 221.7, is made from *p*-nitrotoluene by first chlorinating to obtain 2-chloro-4-nitrotoluene, which is catalytically hydrogenated to the amine and finally sulfonated by heating the sulfate salt in *o*-dichlorobenzene to 100 – 120 °C [58], in sulfolane to 160 °C [59], or in 1,2-dichloroethane in an autoclave to 140 °C [60]. The compound is commonly known as Brilliant Toning Red Amine or Red 2B Acid, and is used as an intermediate in the manufacture of acid azo dyes. The azo dyes and their metallized salts are in turn used as pigments (e.g., Pigment Red 48, C.I. 15865) for paints, printing inks, and plastics [61, 62].

7. Toluidine Toxicology

The *o*-, *m*-, and *p*-toluidines as well as the chlorotoluidines belong to a group of chemicals known as potential "blue lip" compounds. This refers to the serious condition that results from overexposure to toluidines via inhalation, skin absorption, or even ingestion. All the toluidines

Table 2. Toxicity data for the isomeric toluidines [63]

	o-Toluidine	*m*-Toluidine	*p*-Toluidine
Inhalation (LC_{50})	ND∗	ND	ND
Humans (TCL_0)∗∗	25 mg/m^3	ND	ND
Ingestion, mg/kg (LC_{50})			
Rats	670	450	656
Mice	520	470	330
Rabbits	840	ND	270
Skin Contact :			
Rabbits	LD_{50} (3250 mg/kg)	mildly irritating (500 mg/24 h)	irritating (500 mg/24 h)
Eye Contact :			
Rabbits	corneal damage	mildly irritating (20 mg/24 h)	severe irritation (100 mg/24 h)

∗ ND = not determined.
∗∗ TLC_0 = lowest published toxic concentration.

are easily absorbed through the skin and mucous membranes.

Toluidines in the blood stream cause the conversion of hemoglobin to methemoglobin. The latter does not combine with oxygen, and in high concentrations renders the blood stream incapable of carrying oxygen from the lungs to the rest of the body. The earliest manifestation of poisoning is a bluish discoloration (*cyanosis*) of the lips, mucous membranes, fingernail beds, earlobes, and tongue. Minor levels of oxygen deficiency lead to a temporary sense of well-being and exhilaration. As the lack of oxygen increases, such symptoms as headache, drowsiness, and occasional nausea and vomiting appear. More profound decreases in blood oxygen lead to stupor, unconsciousness, and even death if treatment is not obtained immediately. All the toluidines are considered skin and eye irritants, and may cause an allergic skin reaction in some people. Pre-existing diseases of the central nervous system, cardiovascular system, liver, or bone marrow may be aggravated by excessive exposure to the toluidines. Toxicity characteristics are summarized in Table 2.

The December 1990 NIOSH Alert associated worker exposure to a combination of aniline and *o*-toluidine with an increased risk of bladder cancer; the effects of aniline and *o*-toluidine could not be separated. NIOSH concluded that *o*-toluidine was the more likely agent to be responsible for the observed bladder cancers [64]. No studies currently described in the literature directly link worker exposure to *m*- and *p*-toluidine to a carcinogenic effect in humans.

o-Toluidine, as the hydrochloride, has been tested for carcinogenicity in mice and rats by oral administration, and it was found to produce neoplasms at various sites in both species [65, 66]. No neoplasms were observed following subcutaneous injection in hamsters [67]. *p*-Toluidine showed cancerous potential in mice but not in rats, and *m*-toluidine did not produce definitive cancerous activity in either animal species. All three toluidines have been assigned a TLV of 2 ppm.

Chlorinated toluidines have received considerable attention as potential carcinogens. Animal tests have shown both 4-chloro-*o*-toluidine and 5-chloro-*o*-toluidine to be carcinogenic in mice, but not in rats [68, 69]. No convincing evidence was found for carcinogenicity in mice or rats with 3-chloro-*p*-toluidine [70]. One study established a strong correlation between worker exposure to 4-chloro-*o*-toluidine and increased incidence of bladder cancer [71, 72]. On the basis of this study a commission of the Deutsche Forschungsgemeinschaft categorized the compound as a human carcinogen, making it the first example of a monocyclic aromatic amine to be so designated.

All toxicity data indicate that care should be taken to minimize exposure when working with any toluidine, and extreme caution should be exercised when working with *o*-toluidine and its derivatives.

1. Isotopes of Transuranium Elements

Of the transuranium elements only the first ones – neptunium (Np), plutonium (Pu) (→ Plutonium and Plutonium Compounds), americium (Am), curium (Cm), and californium (Cf) – are of some technical relevance. All the other transuranium elements are short-lived, and of those with higher masses only few atoms have been synthesized.

Neptunium, plutonium, americium and curium are byproducts of nuclear energy generation. Except for plutonium, they are regarded as waste.

Neptunium, ^{239}Np, was the first transuranium nuclide to be discovered, by MCMILLAN and ABELSON in 1940. The isotope with the longest half-life, ^{237}Np with 2.14×10^6 years (Table 1), is used to study the chemical and physical properties of this element. It has accumulated on a tonnage scale in nuclear energy generation where it is formed by two reactions:

$$^{238}\mathrm{U}(n,2n)^{237}\mathrm{U}\xrightarrow[6.75\,d]{\beta^-}{}^{237}\mathrm{Np}$$

$$^{235}\mathrm{U}(n,\gamma)^{236}\mathrm{U}(n,\gamma)^{237}\mathrm{U}\xrightarrow[6.75\,d]{\beta^-}{}^{237}\mathrm{Np}$$

In light water reactor fuels, the second reaction is dominant.

^{237}Np can be regarded as the parent nuclide of the extinct decay chain $(4n+1)$ (see Fig. 5).

The americium isotope ^{241}Am was first discovered in 1944/45 by SEABORG and others. Like in nuclear power stations, it was formed by successive neutron capture by ^{239}Pu and subsequent decay of ^{241}Pu:

$$^{239}\mathrm{Pu}(n,\gamma)^{240}\mathrm{Pu}(n,\gamma)^{241}\mathrm{Pu}\xrightarrow[14.89\,a]{\beta^-}{}^{241}\mathrm{Am}\,(432\,a)$$

This nuclide, together with the longer-lived isotope ^{243}Am (7.38×10^3 a), is contained in spent nuclear fuels on a tonnage scale. The shorter-lived ^{242m}Am (141 a) is only present in low concentration in spent light water reactor fuels because of its high thermal fission cross section of 6600 barn, but accumulates in higher concentration in fast reactors.

Curium is the heaviest transuranium element produced on a tonnage scale in nuclear power stations. ^{242}Cm was the first of its isotopes to be discovered, in 1944 by SEABORG, JAMES and GHIORSO according to the reaction:

$$^{239}\mathrm{Pu}\,(\alpha,n)\,^{242}\mathrm{Cm}\,(162.8\,d)$$

They produced this nuclide by means of cyclotron-accelerated helium ions, which differs from the formation in nuclear fuels, where curium is formed by neutron capture of americium nuclides with successive β-decay. Neutron capture by the curium isotopes builds up the chain of heavier curium isotopes up to mass 248 (see Fig. 1 and Table 1).

Berkelium was first produced via a nuclear reaction by bombarding ^{241}Am with accelerated α-particles in 1949:

$$^{241}\mathrm{Am}\,(\alpha,2n)\,^{243}\mathrm{Bk}$$

There are two long-lived isotopes with mass numbers 247 and 249. The latter is part of the chain producing californium by neutron irradiation of ^{248}Cm (Table 1).

Table 1. Nuclear properties of long-lived transuranium isotopes

Isotope	Half-life, a	Decay *	Main radiation, MeV	Thermal cross section, barn		Minimal critical mass in water, g	Minimal critical mass as metal sphere with steel reflector, kg
				Capture	Fission		
^{236}Np	1.55×10^5	EC, β	0.163 (γ)		2500		
^{237}Np	2.14×10^6	α	4.788 (51 %) 4.770 (19 %)	169	0.02		55
^{241}Am	432	α	5.486 (84 %) 5.443 (13 %)	83.6 + 748	3.15		34
^{242m}Am	141	α	5.207 (89 %) 5.141 (6.0 %)	1400	6600	19	3.8
^{243}Am	7.38×10^3	α	5.277 (88 %) 5.234 (11 %)	75 + 4	<0.07		36
^{242}Cm	0.45 6.1×10^6	α SF	6.113 (74 %) 6.070 (26 %)	16	<5		
^{243}Cm	28.5	α	5.785 (73 %) 5.742 (11 %)	225	600	122	
^{244}Cm	18.1 1.35×10^7	α SF	5.805 (76 %) 5.764 (24 %)	14	1.2		5.4
^{245}Cm	8.5×10^3	α	5.362 (93 %)	345	2020	41	
^{246}Cm	4.7×10^3	α	5.386 (79 %)	1.3	0.17		
^{247}Cm	1.6×10^7	α	4.869 (71 %)	60	90	2050	
^{248}Cm	3.4×10^5	α	5.078 (82 %)	4	0.34		
^{247}Bk	1.4×10^3	α	5.712 (17 %) 5.532 (45 %)	?	?		
^{249}Cf	351 6×10^{10}	α SF	5.812 (84 %)	465	1660	70	
^{250}Cf	13.1 1.7×10^4	α SF	6.031 (83 %)	2030	<350		
^{251}Cf	898	α	5.851 (27 %) 5.677 (35 %)	2850	4300	22	
^{252}Cf	2.64	α (97 %) SF (3.1 %)	6.118 (84 %)	20.4	32		

* $\alpha = \alpha$-decay, $\beta = \beta$-decay, SF = spontaneous fission, EC = electron capture.

Californium is the transuranium element with the highest atomic number so far discovered that has isotopes with half-lifes longer than years (Table 1). The first nuclide to be synthesized was ^{245}Cf, obtained by bombarding ^{242}Cm with cyclotron-accelerated helium ions according to the reaction ^{242}Cm (α,n) ^{245}Cf in 1950 by Thompson, Street, Ghiorso, and Seaborg.

The heavier transuranium elements einsteinium (99) and fermium (100) were first detected in the fall-out of an atom bomb test (Bikini Atoll, 1952). They have since been produced by multiple neutron capture of californium targets. The higher transuranium elements (up to 116) are obtained by nuclear reactions of heavy ions on Pb or Bi targets (Table 2).

2. Properties of Transuranium Elements

The elements up to the proton number 103 belong to the actinide elements where, similar to the lanthanides, an inner f shell is filled (in the case of the actinides, $5f$). From 104 to 110, the $6d$ and $7p$ shells are completed.

2.1. Physical Properties

Neptunium, americium and curium are metals with silvery appearance and malleability like uranium metal. When they are exposed to air, an oxide layer readily forms. When heated, the metals undergo one or two phase transitions (Ta-

Figure 1. Buildup chain of long-lived actinides in nuclear fuels, with major and minor pathways (dashed lines symbolize short-lived radioactive decay)

ble 3) before melting. They densify under pressure, passing through different phases to an α-U type structure.

Figure 2. Phase diagram of Np – O (L = liquid phase; L_1, L_2 have different oxygen contents)

2.2. Chemical Properties

Contrary to the lanthanides, the lighter actinides show a large variety of valences and consequently form a wealth of chemical compounds.

Neptunium forms numerous compounds (hydrides, halogenides, chalgonides, pnictides) and organo-complexes, some of which are listed in Tables 4 and 5. Similar to thorium, it reacts with oxygen to give neptunium dioxide (NpO_2); oxides with lower oxidation states cannot be obtained (see Fig. 2). Only dehydration of tri- or pentavalent neptunium hydroxides yields other oxides. In ternary oxides with alkali and alkaline earth elements higher oxidation states (5+, 6+, 7+) are observed. Like plutonium, five neptunium ions with different oxidation states exist in aqueous solution, easily distinguished by their characteristic colors which range from blue or violet (Np^{3+}) over yellow-green (Np^{4+}) to green (NpO_2^+), and pink (NpO_2^{2+}) to brownish red (NpO_3^+). The oxidation potentials in acid solution are:

Table 2. Discovery of the transcalifornium elements [4]

Proton Number	Element ∗	Symbol	Discovered by	By the reaction	First isotope	Longest-lived isotope

∗ Names are those proposed by IUPAC in 1995 and due for confirmation in 1997. Previous names were: 102 Nobelium (No); 104 Rutherfordium (Rf); 105 Hahnium (Ha); 106 Rutherfordium (Rf), since 1994; 107 Nielsbohrium (Ns); 108 Hassium (Hs).

Like plutonium, neptunium can be present simultaneously in different oxidation states in solution, which makes its isolation from other nuclides difficult.

Americium. A large variety of compounds of americium have been synthesized and described. Americium reacts with oxygen to give the sesqui- and dioxides (Fig. 3).

Figure 3. Am – O phase diagram. A = hexagonal Am_2O_3; C = low-temperature bcc Am_2O_3; C′ = high-temperature bcc Am_2O_3; γ, γ_1, γ_2 = fcc AmO_{2-x}

Like neptunium, higher oxidation states exist in ternary oxides with alkaline elements. There is an AmH_{2+x} (fcc) phase, which is isostructural with most of the lanthanide, plutonium, and neptunium dihydrides. A trigonal phase close to AmH_3 has also been observed. Halogenides, chalcogenides and pnictides of Am have been obtained; some trivalent Am compounds are listed in Table 4. Complexes with organic ligands that have been used in large-scale Am separation are listed in Table 5. In aqueous solution, americium can occur in five oxidation states: pink or yellow Am^{3+}, yellow AmO_2^+ and rum-colored AmO_2^{2+}. The colors of the other oxidation states are unknown. The oxidation potentials are given for 1 M $HClO_4$:

In basic media, Am can be stabilized in higher oxidation states than +3, which has been exploited for Am separation. The oxidation potentials are:

Curium. Unlike the lighter actinides, curium exists only in the trivalent and tetravalent states. Since it can be obtained in gram amounts, its compounds have been synthesized and described. Two oxides exist: the sesquioxide Cm_2O_3 and the dioxide CmO_2. Trivalent curium forms binary compounds analogous to those of americium (Table 4) and complexes with organic ligands that are employed in Cm separation (Table 5). In aqueous solution, only the pale green trivalent ion is stable, because of the high oxidation potential of the tetravalent ion:

$$Cm^{4+} \xrightarrow{+3.1\,V} Cm^{3+} \xrightarrow{-2.06\,V} Cm$$

Californium has found widespread use as a spontaneous-fission neutron source; the properties of the oxide and halides are listed in Tables 4 and 5. Organic complexes used for Cf separation are listed in Table 5.

3. Production

Spent nuclear fuels are the only significant source of the lighter transuranium elements. The most abundant element is plutonium. Its recovery and use for energy production are described in → Nuclear Technology, Chap. 5.3.3., → Nuclear Technology, Chap. 5.4.

The amount of transuranium elements contained in a spent fuel varies for each reactor type. For common pressurized water reactors with an initial ^{235}U enrichment of 3.2 % and with a typical burnup of 33 GWd/t, the transuranium content of 1 t of freshly discharged fuel is:

Np	430 g
Pu	9500 g
Am	120 g
Cm	40 g
Bk	0.6 µg
Cf	11 µg

The masses of the lighter transuranium elements which will have accumulated by the year 2000, assuming an installed nuclear electrical energy generating capacity of 514 MW_e and excluding the material in the former Soviet Union is as follows:

^{237}Np	38 t
^{241}Am	34 t
^{243}Am	7 t
^{242}Cm	0.4 t
^{244}Cm	2.2 t

The separation of neptunium from spent nuclear fuels is achieved in two ways: by a modified PUREX process (→ Nuclear Technology, Chap. 5.4.) or from the high-level waste stream of this process. By carefully adjusting the oxidation state of neptunium and extending the extraction stages of the PUREX process, neptunium can be co-extracted with uranium and plutonium. Plutonium is stripped as Pu^{3+} under conditions where neptunium remains dissolved as Np^{4+}, and neptunium can then be stripped selectively from uranium as NpO_2^+.

The americium contained in spent nuclear fuel, like curium, remains together with most of the fission products in the high-level waste of nuclear fuel reprocessing.

Table 5. Stability constants of transuranium elements with inorganic and organic ligands

Since ^{241}Am accumulates in stockpiled plutonium by decay of ^{241}Pu, it can be easily separated, e.g., by sorption of the Pu(IV) hexanitrato complex on anion exchanger and washing Am off with 8 M HNO_3.

Curium has been produced on a kilogram scale by irradiating plutonium, with a yield of about 10 %. After several extraction and ion-exchange processes, remaining Pu is extracted by tri-*n*-butyl phosphate (TBP). Am and Cm chlorides have been extracted with tertiary amines from low acid 11 M LiCl (TRAMEX process) leaving behind the lanthanides, formed by fission of Pu.

Cm has been used as source material to produce gram amounts of californium. Analogous to the TRAMEX process, the lanthanides are removed from the actinides (Am, Cm, Bk, Cf), which are separated by HPLC, e.g., cation exchange where the lanthanides are absorbed from nitrate solution and sequentially eluted with 0.25 M α-hydroxyl isobutyric acid at pH gradually varied from 3.8 to 4.2.

Like the lighter transuranium elements, californium accumulates in spent nuclear fuels.

The longer-lived transuranium nuclides which accumulate in spent fuel as radioactive waste possess considerable capture and/or fission neutron cross sections (Table 1). This offers the possibility of transmuting the radiotoxic alpha-emitting transuranium nuclides into less radiotoxic waste. In handling transuranium elements, it must be borne in mind that a few nuclides have rather low critical masses in solution, as is the case with plutonium. In particular ^{242}Am has a critical mass of only 19 g when dissolved in a water sphere. Also, the metal of certain transuranium nuclides can have critical masses (Table 1) as low as 5.4 kg (for ^{244}Cm). Use for military purposes is limited, due to the high specific radioactivity of most of the nuclides. They would emit too many neutrons which lead to preignition and/or heating to such an extent that the chemical explosive for the implosion would degrade. Only ^{237}Np can be used for nuclear explosives.

Figure 4. Energy spectrum of neutrons emitted from a ^{252}Cf and ^{241}Am-Be source

Figure 5. Extinct decay chain $4n+1$

4. Applications

A commercial application for Np, Am, and Cm – often referred to as minor actinides (MA) – so far has not been found except for negligible amounts of ^{237}Np used to produce ^{238}Pu for thermo-electric devices and for some ^{241}Am to produce pure ^{238}Pu by decay of ^{242}Cm for the same purpose (the decay heat of ^{242}Cm is 120 W/g ^{242}Cm). ^{241}Am is also in use as Am/Be neutron sources by (α,n) reaction (Fig. 4). Some smoke detectors contain ^{241}Am. From the longer-lived Cf nuclides ^{252}Cf serves as a fission neutron source (Fig. 4), and because of its spontaneous fission, fission fragments are used as an ionization source, e.g., in mass spectrometry.

5. Transuranium Elements as Waste

In general, the minor actinides are regarded as waste. All the minor actinides decay into four decay chains, of which three are natural ones with parent nuclides ^{232}Th ($4n$), ^{238}U ($4n+2$), ^{235}U ($4n+3$). (The mass numbers of the three chains obey the given algorithm with n as integer). The chain $4n+1$ (Fig. 5) had disappeared but is now being resurrected thanks to ^{237}Np. Since this nuclide is being produced on a tonne scale, it will testify far into the future that nuclear energy was once used on earth.

Table 6. Annual limits (Bq) of inhalation and ingestion as recommended by ICRP in 1990

Nuclide	Inhalation	Ingestion
^{237}Np	300	3×10^4

Figure 6. Time-dependence of radiotoxicity in a spent LWR fuel (burnup 33 GWd/t), normalized to the radiotoxicity of the uranium ore (dashed line) mined to produce the fuel

The present waste strategy for spent fuel is either direct disposal or to extract only plutonium and uranium, but discharge the other transuranium nuclides together with fission products as vitrified waste to a geological repository.

5.1. Radiotoxicity

The transuranium elements consist mainly of α-emitting nuclides which, when incorporated, are deposited in critical organs, where – as has been shown by animal experiments – malicious tumors may develop. Neptunium tends to stay on the surface of the bones, whereas the transplutonium elements are deposited mainly in the skeleton and liver.

The annual limits of intake for workers are given in Table 6. For the public, limits roughly a factor of 100 lower are set. Inhalation is the most critical intake path; consequently, except for μCi amounts, the transuranium elements are handled in glove-boxes. Because of the possible neutron emission by (α,n) reactions (depending on the other elements present) and spontaneous fission (especially curium and californium) additional shielding by water-filled walls is needed to reduce the occupational dose to the accepted limit. To improve the absorption of the thermalized neutrons, borates or cadmium can be added to the water.

Figure 7. Concept of an accelerator-driven reactor for transmutation of long-lived waste

5.2. Partitioning and Transmutation

The time-dependence of the radiotoxicity resulting from energy generation in a typical light water reactor is shown in Figure 6. Within a few hundred years, the radiotoxicity of fission products drops below that of the uranium ore mined to produce the fresh fuel.

The accumulated transuranium elements would decay over much longer periods. Hence, their transmutation into short-lived or stable nuclides would reduce the radiotoxic hazard for future generations. This view looks only at the source of the radiotoxic hazard as it is posed by the spent fuel in a geological repository. The leaching of the fuel and the eventual migration of nuclides back to the biosphere is a more relevant description of the imminent danger. Also fission product nuclides, even if being of lower

Figure 8. Spent fuel cycle options [mass (mg) of radionuclides discharged from the reactors is normalized to the generated energy (MW · d)]
MA = minor actinides;f.p. = fission produts;LWR = light water reactor;FR = fast reactor;ADR = accelerator-driven reactorIn the case of FR and ADR, the radiotoxic nuclides are transmuted in the reactor. Only the losses during recycling are discharged to the repository. For the FR these amount to ca. 0.3 % per cycle and in total less than 1 %.

quantities, could pose a problem if they are readily soluble (TcO_4^-, Cs^+, I^-) and accumulate in the biosphere.

A radiotoxic nuclide can be transmuted by nuclear reactions into a short-lived or stable one by several methods. Transmutation by photon-induced reactions or by charged particles seem to have technical difficulties. The most promising methods are transmutation by neutron capture or neutron-induced fission. Existing power stations could be used, but also newly-developed dedicated burner reactors driven by accelerators.

The main feature of the concept is a neutron-spallation source in which accelerated charged particles of about 1 GeV strike an initially non-radioactive heavy element target (e.g., Pb), the spallated nuclei produce a neutron shower, with up to 50 neutrons per incident particle. In an appropriate setup, a dense neutron flux is induced in the surrounding, previously subcritical fission reactor (Fig. 7). This is the unique safety feature of an accelerator-driven reactor compared to existing ones: as soon as the accelerator beam is turned off, the reactor is shut down.

To define a reduction of the nuclear hazard, the direct storage of spent light water reactor fuel is taken as a reference point. Figure 8 compares it to the concept of plutonium recycling in light water reactors and recycling of Np, Pu, Am, Cm, Tc in fast reactors. In the latter case, the radionuclides, which are self-generated by the nuclear reactor, are fed back. Instead of slow decay in a geological repository, they are transmuted faster by storage in the nuclear reactor. The equilibrium concentration given for each reactor fuel corresponds to a partitioning and transmutation cycle loss that gives a 100-fold overall hazard reduction.

1. Definition and Chromophores

1.1. Definition

Di- and triarylmethane dyes [1], [2], [3, p. 381], [4, p. 399] belong to the class of polymethine dyes [5], [6]. They can be considered branched polymethines, the latter being known as cyanines, oxonols, and merocyanines (for a definition see →Methine Dyes and Pigments, Chap. 7.4., →Methine Dyes and Pig-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_179

ments, Chap. 8., →Methine Dyes and Pigments, Chap. 10.3.). The branches are created by two aryl rings, in which the polymethine chain is incorporated, and by another R group bonded to the central methine carbon (**1**).

1

The R group possesses π-electrons or lone pairs of electrons that can interact with the rest of the π-electron system.

The most important electron donor is the amino group. *Triarylmethane dyes* are usually divided into mono-, di-, and triaminotriarylmethane dyes. The triphenylmethane dyes with hydroxyl groups, which form metal complexes, are not classified according to this system. Here the amino-group-containing compounds are assigned to the hydroxytriphenylmethane dyes, since the character of these dyes is determined by the complex-forming hydroxyl groups.

The donor group can also be part of a heterocyclic ring, as in the diphenylindolylmethane dyes. In some di- and triarylmethane dyes, the ring carbon atoms *ortho* to the central methine carbon are bonded via a heteroatom to form a heterocyclic six-membered ring. These include the acridine, xanthene, and thioxanthene dyes.

The suggestion has been made [7] that di- and triarylmethane dyes be called di- and triarylmethine dyes, because the central carbon atom is sp^2 hybridized and not sp^3. Despite the advantage of systematic nomenclature, the old trivial names are used here.

1.2. Chromophores

The diphenylmethyl and triphenylmethyl cations can be considered the basic chromophores of di- and triarylmethane dyes [1], [2], [7], [8]. However, the electronic state of the donor-substituted di- and triarylmethane dyes can be described better by breaking down the chromophore of these dyes into a straight- or branched-chain polymethine subchromophore, respectively, and two ethylene units (from the formal cleavage of the benzene rings) [2]. This model allows the similarities between the di- and triarylmethane dyes and the polymethines to be recognized.

The introduction of two dimethylamino groups into the diphenylmethyl cation gives Michler's hydrol blue (**1**, R = H). This compound shows a strong bathochromic shift and an increase in intensity of the absorption band at the longest wavelength compared with the diphenylmethyl cation [**1**, R = H: λ_{max} (log ε) = 607.5 nm (5.17)]. Donor substituents (R) in diarylmethane dye **1** cause a blue shift of the longest-wavelength absorption band, whereas acceptor groups generally cause a red shift [2].

2

Malachite green (**2**, R = H) has two absorption bands in the visible spectrum at λ_{max} (log ε) = 621 (5.02) and 427.5 nm (4.30). The intense absorption band at longest wavelength, known as the *x* band, is shifted toward the red compared with Michler's hydrol blue. The second band (*y* band) is in the shorter-wavelength part of the spectrum and is significantly weaker. The *x* band is polarized normal to the plane of symmetry of the molecule, and the *y* band along the dyadic axis [1], [2], [7].

The appearance of the *y* band can be explained by using the Hückel molecular orbital (HMO) theory or the Pariser – Parr – Pople (PPP –MO) method [8]. The *x* band in malachite green arises basically from a transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO), and the *y* band from a transition from the next highest occupied molecular orbital (NHOMO) to the LUMO [2]. Figure 1 shows the frontier orbitals and the NHOMO of malachite green with the HMO coefficients, $c_{i,\mu}$, the squares of which correlate with the probability μ of finding the electrons around a particular atom. Positive HMO coefficients $c_{i,\mu}$ are indicated in Figure 1 by filled circles and negative ones by empty circles. The sizes of the circles represent approximately the absolute values of the coefficients.

Figure 1. Frontier orbitals and NHOMO with HMO coefficients $c_{i,\mu}$ and HMO orbital energies ε_i ($\alpha_N = \alpha_C + 1.5\,\beta$, $\beta_{CN} = \beta_{CC}$, where α denotes the Coulomb integral and β the resonance integral)

Replacement of one dimethylamino group in malachite green by a methoxy group brings about energetic stabilization of the lone electron pair interacting with the conjugated π-system and thus a lowering of the energy ε_i of the molecular orbital *i* because of the higher electronegativity of oxygen compared with nitrogen. The coefficients c_i in the position of the substituent are larger in the HOMO and NHOMO than in the LUMO. Thus, the HOMO and NHOMO energies are lowered to a greater extent than the LUMO energy, and the HOMO – LUMO and NHOMO – LUMO energy differences are increased if the dimethylamino group is replaced by a methoxy group. This results in a hypsochromic shift of the *x* and *y* bands. Replacement of the dimethylamino by a diethylamino group results in a bathochromic shift and an increase in intensity of the longest-wavelength absorption band [λ_{max} (log ε) = 629.5 nm (5.08)] because of the more pronounced donor character of the diethylamino group [9].

The effect of cyclic amino groups [9] and other substituents (e.g., methyl [10]) in the amino-substituted phenyl rings on the absorption behavior of di- and triarylmethane dyes has been investigated. Bulky substituents in the *ortho*-position cause steric hindrance, which leads to rotation around the central C – C bond. Substituents in the *meta*-position cause the amino groups to rotate out of the coplanar arrangement. The simple HMO model can no longer be reliably used here [2]. Introduction of a group into the *ortho*-position of the third – the "meso"-phenyl ring in malachite green – causes rotation of the ring around the central C – C bond. This generally leads to an increase in intensity of the *x* band and a decrease in intensity of the *y* band (i.e., a color shift from green to blue [11], [12]). The same effect is observed when the meso-phenyl ring is replaced by a 1-naphthyl group [13].

Substituents in the *meta*- and *para*-positions of the meso-phenyl ring shift the position of the absorption band at longest wavelength, depending on their Hammett constants [11], [12]. If a dimethylamino group is introduced into the *para*-position of the meso-phenyl ring, crystal violet is obtained [(**2**, R = $N(CH_3)_2$], instead of malachite green. The absorption spectrum of the former has a hypsochromically shifted *x* and [λ_{max} (log ε) = 589 nm (5.06)] and no *y* band [9]. Figure 1 shows that in the HOMO, the coefficients in the meso-ring disappear. In **2**, the substituent R therefore affects only the LUMO and NHOMO. If a donor substituent R = $N(CH_3)_2$ is introduced into the phenyl ring of malachite green, the LUMO is destabilized; i.e., the energy is raised, so the HOMO – LUMO difference is increased in crystal violet compared with malachite green. The energy of the NHOMO is raised to such an extent that in crystal violet it becomes the degenerate HOMO and the *y* band thus disappears.

The *hydroxytriarylmethane dyes*, which are isoelectronic with cationic triarylmethane dyes, absorb at a shorter wavelength than the latter. The longest-wavelength absorption band of benzaurin (**3**) is at λ_{max}=585 nm compared with λ_{max}=621 nm in malachite green [2].

3

By bonding two phenyl rings via a *heteroatom bridge* in the 2- and 2′-positions, the yellow acridine dyes (**4a**), the red to violet xanthene dyes (**4b**), or similarly colored thioxanthene dyes (**4c**) in the case of amino-substituted di- or triarylmethane dyes are obtained. The donor effect of the occupied *p*-orbital of the heteroatom on the 2- and 2′-positions in malachite green increases the energy of the LUMO more than that of the HOMO. This results in a larger HOMO–LUMO energy difference and thus a hypsochromic shift of the absorption band at longest wavelength, which is most pronounced in the case of acridine dyes. Because of their rigid molecular skeletons these compounds fluoresce. Hydroxyxanthenes behave similarly (e.g., fluorescein) [2].

4a: X = NR² Acridines
4b: X = O Xanthenes
4c: X = S Thioxanthenes

The direct C–C bonding of the 2- and 2′-positions of malachite green to give the fluorenyl cation (**5**) destablizes the HOMO because of the antibonding interaction of the two centers, and stabilizes the LUMO, which experiences a bonding interaction [14].

5

The electronic spectrum of **5** [λ_{max} (log ε) = 955 (4.28), 850 (4.20), 505 (4.32), 470 nm (4.30)] [8] differs drastically from that of malachite green [λ_{max} (log ε) = 621 (5.02), 427.5 nm (4.30)]. The absorption band of **5** at the longest wavelength is shifted strongly to the red and is significantly weaker in intensity compared to malachite green. The fluorenyl cation (**5**) can be considered a chromophore similar to a diradical (antiaromatic) because its frontier orbitals are almost degenerate [15].

On protonation of crystal violet, the color changes first to green and then to yellow. The green coloration is caused by protonation of one of the dimethylamino groups and can be explained by the appearance of the *y* band. The protonation of another amino group leads to the color change to yellow. Amino groups whose conjugation with the ring system is reduced for steric reasons are readily protonated so the intensity of the absorption bands is lowered in comparison with systems having unhindered conjugation because of the proportion of protonated species. In an alkaline medium, decoloration occurs because of formation of triphenylmethanol (**6**) [2].

6

Color formers are very sensitive to the addition of acids and solvents. In acid, crystal violet lactone (**7**) is only partially converted to the colored carboxylic acid (**8**) with opening of the lactone ring [λ_{max} (log ε) = 603 nm (4.41) in methanol – acetic acid (1 : 1)]

The acid is in equilibrium with the colorless lactones protonated on the nitrogen. In very polar solvents such as trifluoroethanol, hexafluoroisopropanol, or phenol, the lactone ring opens to give the zwitterion **9**. The longest-wavelength band of **9** [λ_{max} (log ε) = 593 nm (4.91) in hexafluoroisopropanol] is shifted hypsochromically compared with that of **8**. As in

the case of rhodamine dyes [16], this reaction is a solvent-dependent intramolecular Lewis acid – base equilibrium. The high intensity of the band shows that the equilibrium is shifted strongly to the zwitterionic compound. The electronic spectrum of *fluoran* (**10**), a black color former, has two bands of the same intensity in the visible region [λ_{max} (log ε) = 589 (4.24), 449 nm (4.23) in acetic acid; λ_{max} (log ε) = 554 (4.28), 448 nm (4.26) in 2,2,2-trifluoroethanol] [17], [18]. Here, the equilibrium lies completely on the side of the ring-opened compound. This is verified by comparison with the electronic spectrum of the black ester **11** [λ_{max} (log ε) = 584 (4.26), 447 nm (4.21) in acetonitrile] [17].

10

11

2. History and Economic Importance

2.1. History

The triphenylmethane dyes are among the oldest industrially product dyes. At first they were prepared by methods discovered empirically, without knowledge of their constitution. The first industrial production process for fuchsin was developed by VERGUIN in 1859. In 1861, LAUTH synthesized methyl violet by oxidizing dimethylaniline. Fuchsin was converted into blue dyes with aniline by NICHOLSON in 1862.

In 1876, MICHLER successfully reacted phosgene with dimethylaniline to give 4,4′-bis(dimethylamino)benzophenone. This compound, known as Michler's ketone, has been a starting material for many important triphenylmethane dyes [19]. In 1883, CARO and KERN produced crystal violet from phosgene and dimethylaniline. Malachite green was obtained in 1877 by O. FISCHER from benzaldehyde and dimethylaniline by a process still used industrially today [20]. SANDMEYER and SCHMID isolated a chloro-substituted product of malachite green in 1896. All these dyes are still economically important.

In 1953, ZOLLINGER, WEGMANN, and RHYNER found that Michler's hydrol [21] and mono-, di-, and triaminotriphenylmethane and xanthene dyes [22] are all surprisingly lightfast on polyacrylonitrile fibers. In 1971, KAST, BAUMANN, and MAYER developed a process for the catalytic oxidation of leuco triarylmethane dyes with atmospheric oxygen [23]. The use of crystal violet lactone for the production of self-duplicating paper has been known since 1963 [24].

Acid triphenylmethane dyes were initially produced by sulfonation of basic (cationic) dyes. Aniline blue, which is soluble in alcohol, was thus converted by NICHOLSON in 1862 into a form suitable for dyeing. Acid triphenylmethane dyes based on benzyl-substituted aniline were found to be particularly effective for dyeing wool. Introduction of a sulfonic acid group *ortho* to the methine carbon was a considerable advance in efforts to improve alkali fastness. The first dye of this type was patent blue V, which was obtained by HERMANN in 1888 by treating 3-hydroxybenzaldehyde with diethylaniline, followed by sulfonation.

The first *hydroxytriphenylmethane dye*, rosolic acid, was synthesized in 1834 by RUNGE. Dyes with practical applications, however, were produced only after carboxyl groups *ortho* to the hydroxyl group were introduced by SANDMEYER in 1889. The condensation of *ortho*-substituted benzaldehydes with 2-hydroxy-3-methylbenzoic acid gave dyes that could be converted into metal complexes on wool by aftertreatment with chromium compounds (CONZETTI, 1906). They give clear washfast blue dyes that are still used today.

In 1871, VON BAEYER prepared *fluorescein* by condensation of phthalic anhydride with resorcinol, from which H. CARO, together with VON BAEYER, produced eosin by bromination. The first *rhodamine dyes* were described by BASF in 1887 and the first *sulforhodamines* by STEINER in 1906.

Xanthene lactones have achieved considerable economic importance as chromogenic substances. The first fluorans, which are suitable for self-duplicating paper, were produced by Fuji in 1967. They were used to produce orange and green colorations. A fluoran-based uniform black dye was synthesized in 1969 by NCR and is still important today.

2.2. Economic Importance

The diphenyl- and triphenylmethane and xanthene dyes have achieved considerable economic importance because of their color strength and brilliance. In 1993, ca. 9000 t of *basic di- and triphenylmethane dyes* and ca. 4000 t of *xanthene dyes* were sold. Crystal violet, methyl violet, malachite green, auramine, and rhodamine B are suitable for many purposes and belong to the economically most important dyes.

About 2500 t of *acid diaminotriphenylmethane dyes* were sold in 1993, 1500 t of which were patent blue AE. Of the *sulfonated triaminotriphenylmethane dyes*, whose sales are estimated to be 4000 t, the alkali blue and reflex blue dyes with betaine character have achieved a market volume of ca. 3000 t. They are used mainly in the printing industry to brighten carbon black.

The demand for *chrome dyes* for wool is slightly less than 1000 t.

The demand for *color formers* has increased significantly since the late 1980s. In 1993, ca. 8000 t of color formers were used, half for producing self-duplicating paper and half for producing thermosensitive paper for fax machines. Crystal violet lactone and fluorans are particularly important here.

3. Production

Condensation Reactions. Many triaminotriarylmethane dyes can be produced by condensation of Michler's ketone (**12**) with aromatic amines. The ketone must generally be activated with phosgene or phosphorus oxychloride, whereby a reactive blue chloro compound (**13**) is formed from the intermediate geminal dichloride. With *N*-phenyl-1-naphthylamine, for example, **13** reacts to form Victoria blue B (**14**):

Michler's hydrol (**15**) is even more reactive. It can be obtained by reduction of Michler's ketone with zinc dust [25] or sodium borohydride [26]. Condensation of the hydrol with 3-dimethylaminobenzoic acid (**16**) gives leuco crystal violet carboxylic acid (**17**). The latter is then oxidized to crystal violet lactone.

A leuco compound is also obtained when a benzaldehyde derivative is treated with 2 mol equivalents of an aniline derivative. Leuco malachite green (**20**) is thus formed from benzaldehyde (**18**) and dimethylaniline (**19**):

With benzaldehyde-2-sulfonic and benzaldehyde-2,4-disulfonic acids, important acid dyes are synthesized via this reaction. They are known as patent blue dyes.

Crystal violet (**23**) can be produced directly from formaldehyde and dimethylaniline. The methane base (**21**), *N,N,N′,N′*-tetramethyl-4,4′-methylenedianiline, is formed initially. This is then oxidized to Michler's hydrol (**15**), which condenses with another molecule of dimethylaniline to give leuco crystal violet (**22**). The latter is converted into the dye in a second oxidation step. Pararosaniline, methyl violet and Victoria blue can also be obtained by this reaction sequence:

In the past, alkali dichromates and lead dioxide were used mainly for the oxidation. Because of the toxicity of heavy metals, manganese dioxide has been used instead for some processes [27–29]. The reduction product formed can be recycled by reoxidation to manganese dioxide.

Novel processes use catalytic oxidation with atmospheric oxygen or hydrogen peroxide. They are economical and environmentally acceptable. Both the oxidation of leuco malachite green [30] and the oxidative production of crystal violet [31] from formaldehyde and dimethylaniline can be carried out in glacial acetic acid in the presence of catalytic quantities of 2,3,5,6-tetrachloro-1,4-benzoquinone (chloranil) and (5,14-dihydrodibenzo[*b,i*][1, 4,8,11]tetraazacyclotetradecinato)iron(II) [(tetraaza[14]annulene)iron] using atmospheric oxygen. Vanadium and molybdenum catalysts have also been recommended for the oxidation to give triphenylmethane dyes [32]. Oxidation with atmospheric oxygen and nitrous gases in the presence of chloranil has the advantage of a homogeneous reaction medium [33–35]. A mixture of copper sulfate, sodium chlorate, and chloranil has also been used for oxidizing leuco compounds [36]. Oxidation to acid triphenylmethane dyes can be carried out by using hydrogen peroxide in the presence of (tetraaza[14]annulene)iron [37] or another transition-metal catalyst [38].

Nucleophilic substitution of chlorine, sulfonic acid, or amino groups by aromatic amines is a common process for producing triaminotriarylmethane dyes. Spirit blue (**26**) can be formed from the trichlorotriphenylmethyl cation (**24**) [39], [40] and from pararosaniline (**25**) [41], [42] by reaction with aniline:

In the production of C.I. Acid Blue 90 a *p*-sulfonyl group is replaced by *p*-phenetidine [43].

Production of Xanthene Dyes. The most important starting material for xanthene dyes is phthalic anhydride. It reacts with 3-diethylaminophenol in the molten state to give rhodamine B, and with resorcinol to give fluorescein. For unsymmetrical xanthene dyes, dihydroxybenzoyl- (**27**) or an aminohydroxybenzoylbenzoic acid (**28**) is required:

27

28

These compounds can condense and cyclize with resorcinol or substituted 3-aminophenols. Nucleophilic substitution of chlorine by amines leads to xanthene dyes, which contain a sulfonic acid group [44] or hydrogen [45] instead of the carboxyl group.

In the acidic condensation of (4-diethylamino-2-hydroxy)benzoylbenzoic acid (**28**) with *para*-substituted phenols or phenol ethers, attack occurs at the *ortho* position. The phthalide formed (**29**) cyclizes readily in alkali to form a fluoran (**30**). A black color former is obtained in good yield by reacting **28** with 4-methoxy-3-methyldiphenylamine. The cyclization involves nucleophilic substitution with loss of methanol [46]:

29

30

4. Uses

Basic triphenylmethane dyes are used for dyeing paper, coconut fibers, jute, and other lignin-containing substrates. In the office equipment industry, they are used in the production of ballpoint pastes, fountain pen inks, stamping inks, and hectographic and carbon copy paper. They are also used to dye detergents, seed dressers, plant protection agents, fertilizers, and antifreezes.

An important application for basic dyes and those with betaine character is brightening carbon black for printing inks. By incorporating the dyes into carbon black, a deep black can be produced from the otherwise brownish color. By precipitation with heteropolyacids based on phosphorus or silicon with molybdenum, tungsten, or both, brilliant Fanal pigments (trade mark of BASF) are produced for the printing industry.

Xanthene dyes are used for dyeing wood, paper, fountain pen inks, and cosmetic articles. Lightfast, brilliant red Fanal pigments can be produced from basic rhodamine dyes and heteropolyacids.

Crystal violet lactone is used in the production of self-duplicating paper. *Fluorans* are also used for this purpose and for heat-sensitive paper for fax machines.

5. Diphenylmethane Dyes

Among the diphenylmethane dyes are the salts of substituted bis(*p*-aminophenyl)methanols and diaminobenzophenoneimines. The most important representatives are Michler's hydrol and auramine.

5.1. Michler's Hydrol and Derivatives

Michler's hydrol [*119-58-4*], bis(4-dimethylaminophenyl)methanol (**15**), is produced by oxidation of bis(4-dimethylaminophenyl)methane (*N,N,N′,N′*-tetramethyl-4,4′-methylenedianiline) [*101-61-1*] with lead dioxide. A patent describes the oxidation with

hydrogen peroxide in the presence of the enzyme peroxidase [47]. Michler's hydrol can also be obtained by reduction of Michler's ketone [*90-94-8*] using zinc dust [25] or sodium borohydride [26], [48].

In the presence of acid, the hydroxyl group can be eliminated from Michler's hydrol giving *Michler's hydrol blue* [*14844-71-4*] (**31**) – a deep blue salt that is readily destructed by hydrolysis. It can be stabilized by complex anions such as tetrachlorozincate or phosphotungstomolybdate [49].

15 **31**

Michler's hydrol and related compounds are intermediates in the production of special triphenylmethane dyes.

Derivatives formed by reaction of Michler's hydrol with sulfinic acids or aromatic amines have been recommended as chromogenic compounds for the production of carbon-free copy paper. *Bis(4-dimethylaminophenyl)methyl(4-tolyl) sulfone* (**32**) has achieved industrial importance

32

The compound is obtained by treating Michler's hydrol with sodium 4-toluenesulfinate in glacial acetic acid followed by precipitation with ethanol [50]. Bis(4-dimethylaminophenyl)methyl(4-tolyl) sulfone (**32**) is produced best immediately following the synthesis of Michler's hydrol. For example, Michler's ketone can be reduced with sodium borohydride and then reacted with sodium 4-toluenesulfinate [26]. Alternatively, bis(4-dimethylaminophenyl)methane (*N,N,N′,N′*-tetramethyl-4,4′-methylenedianiline) can be oxidized with atmospheric oxygen in glacial acetic acid in the presence of chloranil and salcomine [*N,N′*-bis-(salicylidene)ethylenediimino cobalt(II)] as catalysts, and the product subsequently precipitated with sodium 4-toluenesulfinate [51]. Michler's hydrol can also be produced from 4-dimethylaminobenzaldehyde and *N,N*-dimethylaniline in the presence of urea. Bis-(4-dimethylaminophenyl)methyl(4-tolyl) sulfone is then obtained by addition of 4-toluenesulfinate [52].

The reaction products of Michler's hydrol with thiophenols [53], azides [54], oximes [55], [56], esters and amides of α-hydroxycarboxylic acids [57], and compounds with active methylene groups [58] are chromogenic compounds. They are colorless but turn deep blue when treated with acidic inorganic substances (e.g., kaolin or bentonite).

Production Example. A mixture of 508 g bis(4-dimethylaminophenyl)methane, 10 g chloranil, 20 g salcomine, 1900 g methanol, and 140 g glacial acetic acid is treated with oxygen at 50 °C in a closed vessel. After 32 g oxygen has been absorbed, 193 g sodium 4-toluenesulfinate dihydrate is added. The suspension is then heated under reflux for 2 h. After cooling, it is filtered; the residue is washed with water, dried, and recrystallized from benzene. Yield: 550 g, *mp* 184 – 185 °C.

Derivatives of leuco auramine (**33**) are obtained by condensation of Michler's hydrol with aromatic amines

33

These compounds also give a deep blue coloration with acidic inorganic substances and are suitable for the production of colorless copier paper. The aromatic amines can contain nonionic substituents – for example, halogens [59], alkyl groups [60], hydroxyalkyl groups [61], and carboxylate ester groups [62]. They can also contain anionic groups [63], [64] and are then suitable for use in carbon paper in alco-

hol duplicating processes. The most important anionic groups are the carboxyl [65] and sulfonic acid [66] groups. Cationic groups, such as the trimethylammonium group, have also been described for this application.

Dimeric leuco auramine derivatives are obtained on reacting Michler's hydrol with hexamethylenediamine [67] or 3,3′-dimethoxybenzidine [68], for example.

Aminothiazole and aminobenzothiazole [69] are suitable heterocyclic amines. Morpholine, piperidine, or piperazine [70], and aminoalkylcarboxylic esters [71] can also be reacted successfully with Michler's hydrol. With morpholine and 2,5-dichloroaniline, leuco auramines are obtained, which have been used successfully for transfer printing on polyacrylonitrile materials [72].

5.2. Michler's Ketone, Auramines, and Derivatives

5.2.1. Michler's Ketone

Michler's ketone [*90-94-8*], 4,4′-bis (dimethylamino)benzophenone (**34**), is an important intermediate in the production of triphenylmethane dyes. It is obtained by reaction of dimethylaniline with phosgene. A second synthetic route involves the catalytic oxidation of bis(dimethylaminophenyl)methane [73].

34

Production Example. A mixture of 508 g bis(4-dimethylaminophenyl)methane, 10 g chloranil, and 20 g salcomine is treated with oxygen in 1970 g methanol at 50 °C with vigorous stirring in a closed vessel. After 64 g oxygen has been absorbed, the reaction mixture is allowed to cool, and the precipitated Michler's ketone is collected by suction filtration, washed with methanol, and dried. Yield: 459 g, *mp* 172 – 174 °C.

Uses. A reactive intermediate for the production of triphenylmethane dyes is formed by treating Michler's ketone with thionyl chloride [74]. A large number of investigations have been carried out on the use of Michler's ketone as a photosensitizer [75], [76].

5.2.2. Auramines

Auramine O [*2465-27-2*], bis(4-dimethylaminophenyl)methyleneiminium chloride (**35**) (C.I. Basic Yellow 2, C.I. 41000) and its ethyl homologue, ethylauramine, are brilliant yellow dyes with high color strength. They have worldwide annual sales of ca. 1000 t.

35

Auramine O can be produced from Michler's ketone and ammonium chloride in the presence of zinc chloride. However, the industrial process starts from bis(4-dimethylaminophenyl)-methane, which is heated to 200 °C with ammonium chloride, sulfur, and sodium chloride. 4,4′-Bis(dimethylaminophenyl)thiobenzophenone is formed as an intermediate; this is readily converted into the imine auramine O with ammonia [77].

Ethylauramine [*6358-36-7*], (C.I. Basic Yellow 37, C.I. 41001), the corresponding *N,N,N′,N′*-tetraethyl compound, is produced similarly.

Both dyes are obtained in particularly pure form if the crude melt is converted into the dye base in an organic solvent and the dye salt is then extracted with water after addition of acid [78].

Production Example. A mixture of 62 g bis(4-dimethylaminophenyl)methane, 120 g urea, 23 g sulfur, and 40 g ammonium sulfate is stirred for 3 h at 155 °C, for 1 h at 165 °C, and for 1 h at 175 °C. The melt is transferred to a prepared mixture of 1 L water at 60 °C, 75 g 50 % sodium hydroxide solution, and 250 g trichloroethylene. The mixture is stirred for 15 min. After phase separation, 1 L water is added to the trichloroethylene phase at 70 °C. The pH is adjusted to 5 with dilute sulfuric acid,

and the mixture is stirred for another 15 min. The trichloroethylene layer is separated, and the dye is precipitated from the filtered aqueous solution with 60 g sodium chloride. After cooling, the dye is collected by suction filtration and dried. Ca. 73.2 g auramine hydrochloride is obtained with a purity of 96 %.

Auramine G (**36**) (C.I. Basic Yellow 3, C.I. 41005) is derived from bis(3-methyl-4-methylaminophenyl)methane. It can be prepared according to the process used for auramine O. However, the dye is no longer produced.

36

Uses. Auramine dyes are used for dyeing of leather, jute, tanned cotton, and paints, and as dye components in inking ribbons, ballpoint pastes, and carbon paper. The most important areas of application are in dyeing paper and in flexographic printing. For the latter, a large number of salts are produced, which have a high solubility in ethanol and ethanol – water mixtures (e.g., nitrates, nitrites [79], bromides, iodides [80], salts of alkyl-, aralkyl-, or arylsulfonic acids [81], thiocyanates [82], and phosphates [83]). For dyeing paper, solutions of the hydrochloride in organic solvents (e.g., thiodiglycol [84]) are employed. Tartaric and citric acids have been used as stabilizers here [85].

The chlorides can also be converted into more easily soluble acetates [86] or propionates [87] to obtain highly concentrated solutions. The hydrogensulfates of auramine are also readily soluble [88].

Colored salts based on auramine with tannic acid, phosphomolybdic acid, and preferably phosphotungstomolybdic acid can be used as yellow toner pigments for the development of latent electrostatic images [89]. *Hydroxyethylauramine dyes*, such as the bis(2-hydroxyethylamine) compound, have been used to dye paper [90].

The solubility of auramine dyes in linseed or mineral oil is increased by substitution at the imino nitrogen. These modified dyes are obtained by reaction of the dye base of ethylauramine with an aliphatic amine in benzene. The reaction product of ethylauramine with butylamine can be used in printing inks [91]. Auramines with aromatic substituents on the imino nitrogen can be produced from Michler's ketone and the anion of an aniline derivative, which can be obtained by reaction with ethylmagnesium bromide and subsequent loss of ethane [92].

6. Triphenylmethane Dyes

6.1. Monoaminotriphenylmethane Dyes

6.1.1. Cationic Dyes

The simplest monoaminotriphenylmethane dye (**37**) is yellow and has good lightfastness on polyacrylonitrile fibers [22]. It is obtained by treating 4-chlorobenzotrichloride with benzene in the presence of aluminum trichloride, and subsequent nucleophilic substitution of chlorine by an amino group.

37

Monoaminotriphenylmethane dyes containing additional donor substituents exhibit a bathochromic shift giving red shades. They can be obtained by reacting alkyl- and alkoxy-substituted benzophenones with aromatic amines [93].

Aminoalkoxytriphenylmethane dyes with carboxyl-containing substituents are used in photography as antihalo dyes [94]. Triarylmethane dyes, which contain a 4-oxo-1-naphthylidene group besides an aminophenyl group, have also been described as antihalo dyes. They contain an acylated group *ortho* to the central carbon atom, which is hydrolized by alkali. A nucleophile is thus liberated, which attacks the dye intramolecularly and irreversibly decolorizes it. Suitable nucleophilic groups include oxymethylene [95], aminomethylene [96], and

in particular, the SO_2NHCH_3 group (**38**, **39**) [97], [98].

38 **39**

6.1.2. Nonionic Derivatives (Triphenylmethanol Derivatives and Lactones)

Substituted aminohydroxytriphenylmethanols and their ethers can be used for transfer printing on textile fiber materials containing anionic groups [99] and as color formers for pressure- and heat-sensitive recording paper [100]. Lactones of monoaminotriphenylmethane dyes are yellow to orange color formers [101].

Extensive kinetic studies were carried out on the addition of hydroxyl [102–104], cyanide [105], [106], and azido groups [107] to the central atom of variously substituted triarylmethane dyes with variation of the temperature, the ionic strength, and dielectric constant (by mixing water with aprotic solvents). These studies gave values for the activation enthalpy and information on the transition state and its agreement with a purely electrostatic theoretical model. It was also found that the rate constants for the reaction with hydroxyl ions correlate with the equilibrium constants [108].

Color formers, which give red-violet dyes on loss of a hydroxyl or alkoxy group or a nitrogen-containing base, are obtained by condensing 4,4′-dimethoxybenzophenone with *N*-methyldiphenylamine. Depending on whether a stoichiometric quantity or an excess of ketone is used, the 4,4′-dimethoxy-4″-*N*-methylanilinotriphenylmethyl cation [109], [110] or the dimeric dication containing one *N*-methyldiphenylamine moiety as a bridge is obtained [111]. These dyes can be converted with sodium hydroxide [109], [111], imidazole, or triazole [110] to colorless compounds (**40**, **41**) that can be used as color formers.

40

41

If an *N*-methyldiphenylamine is used, which has an acceptor (e.g., a cyano group) in one *para*-position, a dark violet color former is produced with sodium methoxide [112].

6.2. Diaminotriphenylmethane Dyes

Diaminotriphenylmethane dyes can be divided into cationic dyes; triphenylmethanol derivatives and lactones; and anionic dyes. The latter assume a zwitterionic character if they contain only one sulfonic acid group.

6.2.1. Cationic Dyes

Doebner's violet (**42**) is the simplest diaminotriphenylmethane dye.

42

This dye is obtained by condensing benzotrichloride with 2 mol equivalents of chlorobenzene in the presence of aluminum trichloride and replacing the *p*-chlorine atoms with amino groups [113].

Malachite Green. A dye that is still very important is malachite green [*569-64-2*] (**43**) (C.I. Basic Green 4, C.I. 42000; oxalate [*2437-29-8*]; zinc chloride double salt [*79118-82-4*]; derivatives: C.I. Solvent Green 1, C.I. Pigment Green 4).

43

Malachite green is synthesized by condensation of benzaldehyde with dimethylaniline in sulfuric acid and oxidation of the leuco compound in hydrochloric acid solution with lead dioxide [82], [114] or manganese dioxide [28]. Alternatively, especially for production of liquid dyes, benzaldehyde is condensed with dimethylaniline in acetic acid to give a leuco base, which is then oxidized catalytically with atmospheric oxygen in the presence of (dihydrodibenzotetraaza[14]-annulene)iron and chloranil [30].

Production Example 1. Condensation [3, pp. 381, 389]: A mixture of 930 kg dimethylaniline, 345 kg benzaldehyde, 270 kg 78 % sulfuric acid, and 90 L water is heated to 112 °C under reflux with stirring for 12 h. After addition of a solution of 215 kg anhydrous sodium carbonate in 230 kg water, excess dimethylaniline is removed by steam distillation. The leuco base is separated.

Oxidation [28]: Leuco malachite green (90.3 g) is dissolved in a mixture of 86.5 g concentrated hydrochloric acid and 100 mL water; this solution is then diluted with 500 mL water. After cooling to 0 °C, 91.5 g of a 34 wt % aqueous suspension of manganese dioxide is added. During oxidation the temperature rises to 15 °C. After 15 min, 140 g potassium carbonate and 100 mL toluene are added. The mixture is heated to 55 – 60 °C and filtered with suction over a frit; the frit is washed with 40 mL toluene. The aqueous phase is removed, and the toluene phase is concentrated on a rotary evaporator at 2 kPa and 45 °C. A solution of 33.5 g anhydrous oxalic acid in 150 mL water is added, and the mixture is stirred for 30 min at 45 °C. The residual toluene and water are distilled off at 2 kPa and 45 °C to constant weight. Approximately 121.5 g of ca. 91 % malachite green oxalate (87 % yield) is obtained in the rotary evaporator flask as green crystals, *mp* 137 – 139 °C, Mn content: 1 mg/kg.

Production Example 2 [30]. A mixture of 18.04 kg glacial acetic acid, 7.26 kg dimethylaniline, 0.9 kg urea, and 3.3 kg benzaldehyde is heated under nitrogen to 60 °C for 1 h and then to 95 °C for 4 h. After cooling to 35 °C the nitrogen flow is switched off. 0.15 kg chloranil and 75 g (dihydrodibenzotetraaza[14]annulene)iron are then added. Air is then passed in at 40 °C with vigorous stirring until oxygen absorption is complete. 30 parts of a ca. 40 % solution of malachite green are obtained, yield ca. 95 %.

On further oxidation of malachite green (**43**) with lead dioxide, demethylation occurs; in addition, the quinoneiminium salt (**44**) and benzoic acid are formed [4, pp. 399, 402].

44

The chloride salt of malachite green is readily soluble in water and all polar solvents that are miscible with water. It is therefore suitable for the production of inks for flexographic printing. It cannot be isolated from aqueous solutions by salting out, but can be obtained by addition of a solvent that is immiscible with water [115]. Crystalline malachite green can be precipitated from dilute aqueous solutions as the oxalate (see production example) and as a mixed salt with carboxylic and phosphoric acids [116].

Uses. Malachite green is used to dye paper, leather, inks, and waxes; it produces deep shades on polyacrylonitrile fibers. It is employed in dye mixtures that also give deep shades on polyacrylonitrile fibers, particularly black and navy blue. Malachite green can be used as the phosphomolybdate for quantitative phosphate determination in aqueous solutions [117]. In medical diagnostics, traces of hydrogen peroxide can be detected quantitatively by using leuco malachite green in the presence of a peroxidase [118].

Trade names include Aizen Malachite Green (Hodogaya), Astrazon Green M (Bayer), and Basazol Green 14 L (BASF).

Brilliant green [*633-03-4*] (**45**) (Diamond Green BX, C.I. Basic Green 1, C.I. 42040,

derivative: C.I. Pigment Green 1) is produced from benzaldehyde and diethylaniline similarly to malachite green and is used in the same way. A Michler's ketone-free ink for inking ribbons containing brilliant green has been described [119].

45

Trade names include Aizen Diamond Green GH (Hodogaya), Basazol Green 20 L (BASF), and Brilliant Green NSA (Zeneca).

Rhodulin blue 6 G [*3521-06-0*] (**46**) (C.I. Basic Blue 1, C.I. 42025, derivative: C.I. Pigment Blue 9) and *rhodulin blue B* [*3943-82-6*] (**47**) (C.I. Basic Blue 5, C.I. 42140, derivative: C.I. Pigment Blue 3) are produced by condensation of 2-chlorobenzaldehyde with dimethylaniline and *N*-ethyl-*o*-toluidine, respectively, followed by oxidation. They are used for dyeing polyacrylonitrile and cellulose acetate fibers.

46

47

The nitrates of **46** and **47** are very soluble in organic solvents and are therefore suitable for the production of copier paper, stamping inks, and ballpoint pastes [120].

*Trade names.*Rhodulin blue 6 G: e.g., Aizen Brilliant Basic Cyanine 6 GH (Hodogaya), Astrazon Blue G (Bayer), and Atacryl Blue 6 G (Atlantic Industries). Rhodulin blue B: e.g., Astrazon Blue B (Bayer), Hispacril Blue 5 B (Robama), Orlamar Blue B (Amar Dye-Chem.), and Primocyanin BX (Sumitomo).

The *lightfastness* of diaminotriphenylmethane dyes on polyacrylonitrile fibers is significantly improved if the amino groups carry electron acceptor-substituted alkyl groups, such as fluoroalkyl [121], 2-cyanoethyl [122], or alkylcarboxylic acid esters [123]. Diaminotriphenylmethane dyes with methyl groups *ortho* to the central carbon atom on the phenyl rings bearing the amino groups have improved lightfastness on polyacrylonitrile fibers [124]. The lightfastness of these dyes on natural fibers is low.

Diaminotriphenylmethane dyes with phenylamino groups are obtained by treating benzotrichloride with chlorobenzene in the presence of aluminum trichloride, followed by substitution of aromatic amines for the *p*-chlorine atoms [125]. These dyes can be used for mass dyeing of polyacrylonitrile fibers. Dyes with only one phenylamino group, which are produced by condensation of 4-dialkylaminobenzophenone with diphenylamine, give blue polyacrylonitrile fibers with a green cast [126].

Diaminotriphenylmethane dyes can be used as positive charge stabilizers [127] in electrophotographic toners and as sensitizers in electrophotographic photoreceptors [128]. Diaminotriphenylmethane dyes with polyoxyalkylamino groups are used as readily washable marking inks and color markers [129–131]. Diaminotriphenylmethane dyes, which have been precipitated with phosphomolybdotungstic acid [132] (C.I. Pigment Blue 3 and 9, C.I. Pigment Green 1 and 4) or with acid metal-complex dyes [133], are used as pigments.

Leuco compounds, such as **48** [*15008-36-3*] [134], which are substituted in the aminophenyl rings *ortho* to the central carbon atom, are used as charge-transfer compounds in organic photoconductors [135], [136].

48

Leuco compounds are suitable components for electrochromic materials for displays [137] and

stabilizers for vulcanizable chloroprene rubber [138].

6.2.2. Nonionic Derivatives (Triphenylmethanol and Triphenylmethylamine Derivatives)

Lactones. Diaminotriphenylmethane dyes, which have a carboxyl group *ortho* to the central carbon atom are obtained by condensation of phthalic anhydride with aromatic amines. A lactone ring is formed on neutralization. Malachite green lactone (**49**) formed with dimethylaniline has a poor color strength when used as a color former because of the stability of the lactone. Its applications are therefore limited.

49

Higher color strengths can be achieved by incorporating additional donor groups into the molecule. Phthalic anhydride and *N,N*-diethyl-*m*-toluidine give a benzoylbenzoic acid that can be condensed with tetramethyl-*m*-phenylenediamine to give a violet-gray color former (**50**) [139].

50

After treatment of 2-bromobenzaldehyde with dimethylaniline, the bromine in the leuco malachite green obtained can be replaced by diethyl butylphosphonite. After oxidation and hydrolysis, a green-blue color former (**51**) is produced in alkaline solution [140]:

51

Benzoxazine Derivatives. Other color formers that do not contain lactone units are derived from salicylaldehyde and 4-diethylaminosalicylaldehyde. After condensation – for example, with dimethylaniline – a leuco malachite green derivative is obtained, whose *o*-hydroxyl group can react with phenyl isocyanate. The leuco dye is oxidized, and the *N*-phenylcarbamoyloxy group formed undergoes a cyclization reaction in alkaline solution. A mixture of two color formers **52** and **53** is thus obtained [141].

52

53

Another starting material, which gives a new system of color formers, is 3-dimethylaminoaniline, whose primary amino group has been reacted with ethyl chloroformate to yield ethyl-3-dimethylaminophenylcarbamate. The carbamate can be condensed with 4-diethylamino-4′-methoxybenzophenone to yield a dye that cyclizes in alkaline solution to give a 4,4-diaryl-2-oxobenzo-1,3-oxazine (**54**) [142].

54

If 3-dimethylaminoaniline is acylated with benzoyl chloride and the 3-benzoylaminodimethylaniline is treated with the same benzophenone, a 4,4-diaryl-2-phenyl-1,3-benzoxazine (**55**) with X and Y = H is obtained [143].

55

Color formers that only differ from **55** in that they are derived from a toluylene mixture are of particular interest. A mixture of 90 % X = methyl and Y = H and 10 % X = H and Y = methyl gives a black color former [144] that, in combination with fluorans [145] and bisindolylphthalides or with benzoxazines derived from monoaminotriphenylmethane dyes [146], shows improved intensity and lightfastness.

Quinazoline Derivatives. The *4,4-diaryltetrahydroquinazolones* are also derived from 3-dimethylaminoaniline. The synthesis gives blue color formers in the triaminotriphenylmethane series. After addition of the primary amino group of 3-dimethylaminoaniline to an alkyl or acyl isocyanate, a urea derivative is formed that is converted into a leuco dye by reaction with Michler's hydrol. After oxidation the leuco dye is cyclized to a color former in alkali. The 4,4-diaryltetrahydroquinazolones (**56**) formed have either an alkyl [147] or an acyl [148] group on the nitrogen in the 3-position.

56

Blue color formers are obtained by condensation of Michler's ketone with (2-benzothiazolyl)-3-diethylaminophenylamine. Cyclization gives a *dihydroquinazoline* (**57**) [149].

57

Diaminotriphenylmethane dyes can be converted into color formers by bonding a base to the central carbon atom of a triarylmethane dye. Examples are malachite green [150] and dyes in which the *p*-nitrogen is bridged with the *ortho* position, as in 1-ethyl-2,2,4-trimethyl-1,2,3,4-tetrahydroquinoline, 1,2,3,3-tetramethylindoline [151], or 9-ethylcarbazole [152], [153].

6.2.3. Anionic Dyes

Triarylmethane dyes must contain at least two sulfonic acid groups before they can assume anionic character. These dyes are obtained by condensation of a benzaldehyde derivative with 2 mol equivalents of a substituted aniline. A leuco compound is first formed, which must then be oxidized to give the dye by using lead dioxide, manganese dioxide, or sodium dichromate. The two sulfonic acid groups can be located either on the benzaldehyde or on the aniline derivative.

Patent Blue Range. In 1902 STEINER showed that a sulfonic acid group *ortho* to the central carbon atom imparts particularly good fastness to alkalis. Systematic development led to the patent blue dyes, which have become valuable products for dyeing wool.

One of the first of this series was *patent blue V* [*3536-49-0*] (**58**) (C.I. Acid Blue 3, C.I. Food Blue 5). It is obtained by condensation of 3-hydroxybenzaldehyde with *N,N*-diethylaniline, sulfonation of the leuco base *ortho* and *para* to the hydroxyl group, and oxidation with manganese dioxide [154].

58

A dye with similarly good properties can be produced more easily. *Patent blue VE* [*129-17-9*] (**59**) (C.I. Acid Blue 1, C.I. Food Blue 3, C.I. 42 045, with R = ethyl) does not contain a

hydroxyl group and can be produced directly from 4-formyl-1,3-benzenedisulfonic acid and diethylaniline with subsequent oxidation [155].

59

If diethylaniline is replaced by ethylbenzylaniline in this synthesis, *patent blue AF* (**59**) (C.I. Acid Blue 7, C.I. 42080, R = benzyl) is formed. Both dyes are used for wool.

Trade names. Acid Blue 1 is commercially available as Sulfacid Brilliant Blue 6 J (ICI), and Acid Blue 7 as Sandolan Turquoise E-AS (Sandoz).

The greatest economic importance of some patent blue dyes is in nontextile applications. Acid Blue 1 and 3 are both used in sanitary installations to dye lavatory fresheners or flushing water. *Patent blue AE* [*3844-45-9*] (**60**) (C.I. Acid Blue 9, C.I. Food Blue 2, C.I. 42090, R = SO_3H) can also be used for this purpose. Its leuco compound is obtained from 2-formylbenzenesulfonic acid and *N*-ethyl-*N*-(3-sulfobenzyl)aniline [156] and oxidized by an environmentally acceptable process in the presence of (dihydrodibenzotetraaza[14]annulene)iron as the catalyst with peroxomonosulfuric acid [157] or hydrogen peroxide [37]. In 1993, more than 1000 t of this dye were produced and used in sanitary installations.

Trade names include Basacid Blue 755 (BASF), Sulfacid Brilliant Blue 5 J (ICI), and Neolan Blue E-A (Ciba-Geigy).

Derivatives of N-Ethyl-N-(3-sulfobenzyl)aniline. Dyes that do not belong to the patent blue range and, like C.I. Acid Blue 9, are derived from *N*-ethyl-*N*-(3-sulfobenzyl) aniline include C.I. Acid Green 3 [*4680-78-8*], (**60**, R = H, C.I. Food Green 1, C.I. 42085) and C.I. Acid Green 9 [*4857-81-2*] (**60**, R = Cl, C.I. 42100).

60

The starting material for C.I. Acid Green 3 is benzaldehyde and for C.I. Acid Green 9, *o*-chlorobenzaldehyde. Both dyes are used for wool.

Trade names. Hispacid Green GB (Robama) and Sandolan Brilliant Green E-6 B (Sandoz).

Production Example for Acid Green 3. N-Ethyl-*N*-(3-sulfobenzyl)aniline (1340 kg) is charged as a moist paste to a glass-lined stirred vessel containing 2000 L water, which is equipped with a reflux condenser; 300 kg benzaldehyde is then added. The mixture is heated to 98 – 100 °C for 48 h, and excess benzaldehyde is distilled off. The mixture is diluted to 8000 L with water, and the precipitated leuco acid is dissolved at 80 °C by slow addition of 500 L 30 % sodium hydroxide, resulting in a pH between 7 and 7.2. The solution of the leuco acid is then diluted to 9000 L with water and oxidized to the dye in three portions. Then, 3000 L of the solution and 4000 L of water are cooled to 0 °C in a glass-lined stirred vessel. A 35.5 wt % aqueous solution of 75 kg sodium dichromate is added with vigorous stirring. A solution of 192 kg oxalic acid in 800 L water and 96 kg 78 % sulfuric acid is then charged in one portion, and the mixture is stirred for 15 min at 0 – 10 °C. It is then heated to 50 °C, and the dye is salted out as a colored resinous material with 600 kg sodium sulfate. After stirring for 1 h at 50 °C, 2 kg of a nonionic – polymeric emulsifier [castor oil + poly(ethylene oxide)] is added. After an additional 20 min without stirring, the colored resinous material is drained on drying sheets. Yield: 1640 kg.

Derivatives of Naphthalenesulfonic Acids. Dyes containing naphthalenesulfonic acids require tetraalkylated diaminobenzhydrols (diaminodiphenylmethanols) as condensation partners. *C.I. Acid Green 16* (**61**) (C.I. 44025) is produced by condensation of 4,4′-bis(diethylamino)benzhydrol with 2,7-naphthalenedisulfonic

acid and oxidation of the leuco compound [158]. The dye is used for wool and 50 % wool blends.
Trade Names. Neolan Green E-B (Ciba-Geigy) and Sulfacid Brilliant Green 2 J (ICI).

61

Marking inks can be produced from 4-formyl-1,3-benzenedisulfonic acid and polyoxyethylated aniline. The latter is obtained by treating aniline with 50 – 100 mol ethylene oxide. The marking inks can be washed readily from the substrate and do not leave any permanent coloration on the skin [159].

6.3. Triaminotriphenylmethane Dyes

6.3.1. Cationic Dyes

Pararosaniline and its ring-alkylated derivatives belong to the group of cationic triaminotriphenylmethane dyes, as do the phenylated and alkylated rosanilines and the triaminodiphenylnaphthylmethane dyes of the Victoria blue series.

Pararosaniline [*569-61-9*] (**62**) (parafuchsin, paramagenta, C.I. Basic Red 9, C.I. 42500) is the simplest member of this series.

62

It is produced by condensation of 4-aminobenzaldehyde with aniline [160]; 4-aminobenzyl alcohol with aniline [161]; or 4,4′-diaminodiphenylmethane with aniline [162] in the presence of oxidizing agents such as nitrobenzene, nitrotoluene, azobenzene, or atmospheric oxygen in the presence of iron(II) chloride, arsenic acid, or ammonium or sodium metavanadate [163] at 150 – 170 °C. Pararosaniline can be purified by precipitation from the aniline solution with dodecylbenzene [164]. An aniline-free product is also obtained by converting **62** to the nitrate salt, which is dissolved in aniline and converted into the triphenylmethanol derivative with sodium hydroxide. The triphenylmethanol is isolated and converted with acids into the corresponding dye salts, which are deep red in solution [165].

Uses. Pararosaniline is an intermediate for the production of phenylated rosanilines. It gives a brilliant red dyeing on polyacrylonitrile fibers. In analytical chemistry, pararosaniline can be used to detect aldehydes in biological materials [166] and to determine the content of sulfur dioxide in air [167]. It can also be used to produce a reagent for detecting aromatic aldehydes [166].

Fuchsin [*632-99-5*] (**63**) (rosaniline, magenta, C.I. Basic Violet 14, C.I. 42501) is produced by oxidizing a mixture of aniline and toluidines with nitrobenzene, nitrotoluene, or atmospheric oxygen in the presence of zinc chloride or iron(II) chloride. The methyl group of *p*-toluidine provides the central carbon atom. Fuchsin is the oldest cationic triaminotriphenylmethane dye. The discovery of fuchsin with the methyl group *ortho* to the amino group occurred by chance, because the aniline used contained *o*-toluidine as an impurity.

63

Uses. Fuchsin dyes silk, wool, and paper in brilliant red shades with a blue cast and is used as a microscopic stain.
Trade names include Atacryl Fuchsin (Atlantic Industries), Basic Magenta (Amar Dye-Chem.), and Magenta (W. S. Simpson & Co.).

New fuchsin [*3248-91-7*] (**64**) (C.I. Basic Violet 2, C.I. 42520) is obtained by condensing *N*-methyl-*o*-toluidine with formaldehyde [168] or methylene dichloride [169], or from *N,N*-dimethyl-*o*-toluidine in the presence of nitro compounds as oxidizing agent. Under these conditions methyl groups are eliminated from the nitrogen atom of *N,N*-dimethyl-*o*-toluidine as formaldehyde. These then form the central carbon atom of the dye.

64

New fuchsin can also be produced by reaction of *N*-methyl-*o*-toluidine, *o*-toluidine hydrochloride, and *m*-xylidine with *o*-nitrotoluene and iron(II) chloride [170]. The crude dye obtained by this method can be purified by dissolving it in a mixture of chlorobenzene and dilute hydrochloric acid and cooling it slowly [171]. Stable concentrated solutions of new fuchsin are obtained in a mixture of acetic acid and mono- or polyhydric alcohols as solvent [172]. The tint of new fuchsin is bluer than that of pararosaniline.

Uses. New fuchsin can be used for dyeing polyacrylonitrile, paper, and leather. Hexaazotized new fuchsin can be used to detect proteinases in cell membranes [173].

Trade names. Basic Magenta (Dintex Dyechem PVT) and Ravi Basic Magenta II (Ravi Chem Dye Bombay).

Rosaniline dyes containing carboxyl groups can be used as color or filter layers in photographic materials [174].

Tris(4-hydrazinophenyl)methylium chloride is used for detecting aromatic aldehydes and ketones [175]. It can be produced by diazotization of pararosaniline followed by reduction in the presence of zinc chloride.

Phenylated rosaniline dyes can be produced by two different processes. Pararosaniline is the starting material for the BASF process. It is subjected to acid-catalyzed phenylation with aniline involving elimination of ammonia to give *spirit blue* [*2152-64-9*] (**65**) (Blue II T Base, Opal, C.I. Solvent Blue 23, C.I. 42760). Depending on reaction conditions, one to three phenyl groups can be introduced. The blue dye becomes greener with increasing degree of phenylation.

65

Production Example for Spirit Blue [176]. A mixture of 460 kg pararosaniline, 2450 kg aniline, and 8.5 kg benzoic acid is heated to 180 – 182 °C until the dye has reached the desired color that is tested in an acetic acid – alcohol mixture. This requires ca. $1\,^1/_2 - 2$ h. After the reaction mixture is cooled to 100 °C, it is added to a mixture of hydrochloric acid and water. The dye precipitates and is separated by suction filtration. To remove residual aniline, the product is heated again with dilute hydrochloric acid and the dye is filtered, washed, and dried under vacuum at 100 °C, yield: 682 kg.

The arylation of pararosaniline can also be carried out with toluidines, diamines [41], and alkoxyarylamines [42], as well as aniline. The reflex blue dyes made by Hoechst also contain spirit blue or similar compounds. The synthesis of reflex blue dyes does not start from pararosaniline but from 4,4′,4″-trichlorotriphenylmethyl tetrachloroaluminate, which is obtained from *p*-chlorobenzotrichloride and chlorobenzene in the presence of aluminum trichloride and whose chlorine atoms can be substituted by nucleophiles. Replacing the chlorines with aniline, however, leads to an undesired side reaction. After substitution of the third chlorine atom, the carbon atom *para* to the amino group of another molecule of aniline attacks the central carbon

of triphenylpararosaniline. A molecule of diphenylamine is eliminated, with the formation of diphenylpararosaniline. It is thus very difficult to obtain blue dyes with green casts in good yield according to this method. However, if *m*-toluidine is used instead of aniline, dyes having blue shades with a green cast can be obtained. These cannot be produced by any other process. The reason for the successful reaction with *m*-toluidine is that the *m*-methyl group shields the carbon *para* to the amino group and thus hinders nucleophilic attack at the central carbon atom [39].

Production Example for Tri-m-tolylpararosaniline [39]. Production of 4,4′,4″-trichlorotriphenylmethyl tetrachloro-aluminate: A mixture of 200 g 4-chlorobenzotrichloride in 190 g chlorobenzene is added to a suspension of 127.5 g anhydrous aluminum trichloride in 450 g chlorobenzene with cooling and stirring in such a way that the temperature does not rise above −5 °C. The mixture is stirred for 15 h at −5 °C and then heated to 55 – 60 °C and kept at this temperature for ca. 20 h. After cooling, excess chlorobenzene is removed by suction through an attached glass frit, leaving the condensation product in the form of a thick crystalline precipitate.

Production of tri-*m*-tolylpararosaniline: *m*-Toluidine (613 g) is added to the aluminum complex of 4,4′,4″-trichlorotriphenylmethane, and the mixture is heated to 150 °C for 5 h. The strongly bronzing blue melt is stirred in dilute hydrochloric acid. Small quantities of chlorobenzene are removed by steam distillation, and the crystalline dye is washed until neutral.

The three chlorine atoms in 4,4′,4″-trichlorotriphenylmethyl tetrachloroaluminate differ in their reactivity. Besides symmetrical spirit blue derivatives, unsymmetrical compounds can also be produced. One chlorine atom can first be replaced by a *m*- or *p*-substituted aniline derivative. Aniline or an *o*-substituted aniline can then be substituted for the others [177]. Triphenylpararosanilines can also be produced from diphenylamine derivatives and carbon tetrachloride in the presence of aluminum trichloride [178]. Addition of DMF promotes this reaction [179].

Triphenylpararosaniline sulfates have pigment character and can be used in place of alkali blue [180]. Color lakes made from triphenylpararosanilines and molybdenum- or tungsten-containing heteropolyacids are blue pigments [181], [182].

Methyl Violet. Alkylated pararosaniline dyes are obtained from secondary and tertiary aromatic amines. Methyl violet [*101357-18-0*] (C.I. Basic Violet 1, C.I. 42535, derivatives: C.I. Solvent Violet 8; C.I. Pigment Violet 3, 3 : 3, 27) can be produced by air oxidation of dimethylaniline in the presence of phenol, copper salts, and sodium chloride. A methyl group is eliminated and oxidized to formaldehyde. Further condensation with dimethylaniline and oxidation lead to the dye. Since the partially dealkylated dimethylaniline also takes part in the condensation, methyl violet is a mixture of tetra-, penta-, and hexamethylated pararosanilines.

Production Example [183]. In a cast iron, glass-lined 5-m^3 vessel, 30 kg sodium chloride and 236 kg copper sulfate are dissolved in 1000 L water. Then, 400 kg dimethylaniline and 25 kg phenol are added and the mixture is stirred for 30 min at 20 °C. After increasing the stirrer speed, 222 kg sodium chloride is added in portions of 10 kg/h. In the first 4 h, 12 m^3/h air is blown in; in the subsequent 16 h, 17 m^3/h; and in the last 4 h, 23 m^3/h. At the end of this period the melt contains only traces of dimethylaniline. Formaldehyde must no longer be detectable. After being heated to 100 °C the mixture is drained into a copper trough with stirring, and after being cooled to 50 °C, the supernatant aqueous solution is separated from the melt. The completely cooled melt is ground up and stirred for 12 h in an iron vessel with 1500 L water, 50 kg sodium chloride, and 60 kg 34.5 wt % aqueous sodium hydroxide solution to decompose the copper(I) chloride double salt of the dye. After addition of 60 kg 34.5 wt % aqueous sodium hydroxide solution, the reaction product is added to 2500 L water, and the volume is made up to 8000 L with water. After stirring for 4 h at 20 °C, 180 kg 34.5 wt % aqueous sodium hydroxide solutions added, and the mixture is heated to 95 °C in 6 h. The color base is allowed to settle, ca. 3000 L supernatant alkali is removed, and the volume is again made up to 8000 L with cold water, whereby the temperature is adjusted to 60 °C. A solution of 65 kg sodium sulfide (60 %) in 3000 L water is added with stirring to convert the copper oxide formed in the alkaline liquor into copper sulfide. After

stirring for 2 h, the color base is decanted three times by alternately adding and removing water. The color base is then stirred with 5500 L water and 80 kg 62.5 % sulfuric acid for 1 h in the cold. It is heated to 100 °C and brought into solution with sulfuric acid in a weakly acidic solution. The dye solution is separated from copper sulfide on a filter press and salted out with sodium chloride. After redissolving in water and salting out with sodium chloride, the dye is converted completely to the chloride. After isolation, it is dried in a drum dryer. Yield: 104 kg from 100 kg of reacted dimethylaniline (84.3 %).

Instead of phenol, the addition of a dispersing agent [184] or a nonionic surfactant [185] to the oxidation melt is recommended.

Uses. Methyl violet is readily soluble in organic solvents and is therefore used as the dye salt and dye base (Solvent Violet 8) in many areas of the office equipment industry (e.g., in the production of carbon paper, stamping inks, hectographic inks, and inking ribbons). It is also a component of black dyes for polyacrylonitrile materials.

Trade names include Aizen Methyl Violet RL Special (Hodogaya), Basonyl Violet 600 (BASF), and Paris Violet (Zeneca).

The phosphomolybdotungstate (Pigment Violet 3), copper hexacyanoferrate (Pigment Violet 27) and tannic acid (Pigment Violet 3 : 3) salts of methyl violet are pigments with high color strength used in the production of printing inks.

C.I. Basic Violet 13 [*8004-88-4*], C.I. 42536, is produced by benzylation of methyl violet and consists of a mixture of benzylated tetra-, and pentamethylpararosaniline and hexamethylpararosaniline.

Trade name. Benzyl Violet DSC (Dye Specialties).

Crystal violet [*548-62-9*] (**66**) (C.I. Basic Violet 3, C.I. 42555, derivatives: C.I. Solvent Violet 9, C.I. Pigment Violet 39) is produced by condensation of dimethylaniline and phosgene. 4,4′-Bis(dimethylamino)benzophenone (Michler's ketone) is formed as an intermediate, but is not isolated [186], [187].

66

The production of crystal violet can also be carried out as a one-pot reaction by condensing dimethylaniline with formaldehyde to 4,4′-methylenebis(*N,N*-dimethylaniline), which is reacted with dimethylaniline and simultaneously oxidized to the dye by atmospheric oxygen in the presence of (dihydrodibenzotetraaza[14]annulene)iron and chloranil [188]. Vanadium and molybdenum compounds [32] and nitrous gases [35] can also be used as oxidation catalysts together with chloranil. Crystal violet can be produced by condensation of 4-dimethylaminobenzaldehyde [30] with 2 mol equivalents of dimethylaniline or from 4,4′-bis(dimethylamino)diphenylmethanol with 1 mol equivalent of dimethylaniline and subsequent oxidation of the leuco base.

Production Example [188]. A mixture of 1089 parts dimethylaniline, 90 parts paraformaldehyde, and 1391 parts glacial acetic acid is heated to 70 °C for 1 h. The solution is cooled to 50 °C, treated with 15 parts chloranil and 15 parts (dihydrodibenzotetraaza[14]annulene)iron, and the mixture aerated for 20 h with vigorous stirring. Ca. 800 parts glacial acetic acid are distilled off at reduced pressure and the residue is dissolved in 16 000 parts water at 95 °C. The solution is filtered hot and the dye is precipitated from the filtrate with 3000 parts sodium chloride at pH 1.5. The crystalline dye is collected by suction filtration and washed with 3000 parts dilute sodium chloride solution. Yield: 1050 parts.

Uses. Crystal violet is used in the office equipment industry for the production of indelible pencils, for making stamping and hectographic inks, and for dyeing paper. The color strength in hectographic coloring matter is particularly high if crystal violet is present as the nitrate [189]. The grain hardness of crystal violet or methyl violet is lowered by crystallizing the dye in the presence of poly(ethylene glycol) [190]. Crystal violet can also be used as a component of navy blue and black dyes for

polyacrylonitrile fibers. Ink jet inks containing crystal violet and di(ethylene glycol) butyl ether have high antibacterial activity [191]. The salt of crystal violet and a heteropolyacid has been proposed for detecting phosphorus [192].

Precipitation with phosphomolybdotungstic acid gives a printing ink pigment, C.I. Pigment Violet 39.

Trade names for methyl violet and crystal violet include Basazol Violet 57 L (BASF), Methyl Violet B (Zeneca), Dycosbasic Methyl Violet 2 B (Shanghai Dyestuffs Industries), and Crystal Violet DSC pure (Dye Specialties).

Ethyl violet [*2390-59-2*] (**67**) (C.I. Basic Violet 4, C.I. 42600, derivative: C.I. Pigment Blue 14) is obtained analogously to crystal violet from diethylaniline and phosgene or from diethylaniline and formaldehyde with catalytic oxidation [188].

67

Uses. Ethyl violet is used to dye wood-containing paper. With phosphomolybdotungstic acid, a pigment for printing inks, Pigment Blue 14, is obtained.

Trade names are Ethyl Violet (Dye Specialties) and, for use as a pigment, Halopont Blue RNM (Mobay).

Cationic triaminotriphenylmethane dyes that contain a *phenylamino group* are obtained by treating diaminotriphenylmethane dyes, which have a chlorine atom bonded to the 4-position of the third phenyl group, with aromatic amines [193]. If cyanoethyl groups are present on the two other amino groups of these phenyl-substituted dyes, lightfast coloration of polyacrylonitrile fibers is achieved [194].

Triaminotriphenylmethane dyes with *long alkoxylated amino groups* are used as marking inks [195]. These dyes fulfill the requirements for fugitive inks for temporary marking during fiber production [130].

Victoria blue B [*2580-56-5*] (**68**) (C.I. Basic Blue 26, C.I. 44045, derivatives: C.I. Solvent Blue 4, C.I. Pigment Blue 2) is produced by condensation of Michler's ketone with *N*-phenyl-α-naphthylamine in toluene with phosphorus oxychloride [196] or by catalytic oxidation of the leuco base [188] – formed by oxidation of 4,4′-bis(dimethylaminophenyl)methane in the presence of *N*-phenyl-α-naphthylamine – with air and catalytic quantities of (dihydrodibenzotetraaza[14]annulene)iron and chloranil.

68

Uses. Victoria blue B is used to dye paper and, melted in oleic or stearic acid, as a color base for the production of printing inks.

Trade names are Aizan Victoria Blue BH (Hodogaya), Atlantic Victoria Blue B (Atlantic Industries), and Basazol C Blue 57 L (BASF), for example.

The *N*-methyl derivative of Victoria blue B is commercially available under the name *Victoria blue 4 R* [*2185-87-7*] (C.I. Basic Blue 8, C.I. 42563, derivative: C.I. Solvent Blue 2).

Trade name: Basonyl Blue 633 (BASF).

If the phenylamino group in Victoria blue B is replaced by an ethylamino group, *Victoria blue R* [*2185-86-6*] (C.I. Basic Blue 11, C.I. 44040, derivative: C.I. Pigment Blue 10) is obtained.

Trade name: Dycosbasic Victoria Blue R (Shanghai Dyestuffs Industries) and Victoria Blue RSA (Zeneca).

Victoria blue FBR [*3251-84-1*], (C.I. Basic Blue 55, C.I. 44044) differs from Victoria blue B in that it contains a cyclohexylamino group instead of a phenylamino group. It is more soluble in alcohol than Victoria blue B.

Trade name: Flexo Blue 630 (BASF) [197].

Victoria pure blue BO [*2390-60-5*] (**69**) (C.I. Basic Blue 7, C.I. 42595, C.I. Solvent Blue 5, C.I. Pigment Blue 1, 1 : 2, 62) is produced by treating 4,4′-bis(diethylamino)benzo-

phenone with phosgene to give the ketone dichloride, followed by treatment with *N*-ethyl-α-naphthylamine [198].

69

Victoria blue BO is used to dye paper and in stamping and flexographic printing inks.
Trade names include Basonyl Blue 636, Flexo Blue 636 (BASF), and Mitsui Victoria Pure Blue BO (Mitsui Toatsu Dyes).

Victoria pure blue BO is converted into a color lake with phosphomolybdotungstic acid (Pigment Blue 1), which is used in the printing inks industry for decorative printing. The color lake obtained from Victoria pure blue BO and copper hexacyanoferrate(II), Pigment Blue 62, is used in aqueous printing inks and for shading gravure printing inks for illustrations. A coloring material used in ballpoint inks and pastes consists of the salt of a polysulfonated phthalocyanine and Victoria pure blue BO [199]. Addition of cyanotriacetic acid or ethylenediaminetetraacetic acid gives pigments in the Victoria blue range, which are stable in nitrocellulose [200].
Trade names. Fast Blue Lake (China National Chemicals), Fanal Blue D 6340 (BASF), and Irgalit Blue FR (Ciba-Geigy).

Victoria pure blue FGA [*73309-46-3*] (C.I. Basic Blue 81, C.I. 42 598) is similar to Victoria pure blue BO, but contains a 4-ethoxyphenylamino group instead of an ethylamino group. It is insoluble in cold water and can therefore be used in printing inks with good waterfastness without addition of a laking agent.
Trade name: Flexo Blue 680 (BASF).

Crystal violet tetraphenylborate [201], Victoria blue dyes [202], and substituted triphenylpararosanilines [203] can be used as positive charge stabilizers in electrophotography. Anodized aluminum can be dyed electrolytically with triarylmethane dyes [204].

Leuco compounds of the triaminotriphenylmethane dyes, in which the amino groups are replaced by alkyl [205] or aryl groups [206], have been proposed as color formers for colorless copier paper. Leuco triaminotriphenylmethanes can be used as charge-transfer compounds [207] and photoreceptors [208] in electrophotography and as contrast dyes in photoresists [209]. Leuco bases can also be used for the quantitative detection of ozone [210] and in microencapsulated temperature indicator systems together with an oxidizing agent [211].

6.3.2. Nonionic Derivatives (Triphenylmethanol Derivatives and Lactones)

Colorless compounds derived from triaminotriphenylmethanols and lactones (phthalides) form deeply colored compounds on irradiation or contact with acidic substrates. A film for radiation dose measurement contains the azide of crystal violet, which is converted to the dye on irradiation. The optical density is proportional to the radiation absorbed [212]. The cyanides of crystal violet [213] and new fuchsin [214] give deep colorations under UV light and are therefore suitable for reproduction purposes.

Lactones and Related Compounds. *Crystal violet lactone* [*1552-42-7*] (**70**) is the most important triaminotriphenylphthalide. In 1993, its sales were ca. 800 t worldwide. This color former gives a reddish blue print. Crystal violet lactone can also be used in gas analysis. The blue color of thin layers, which contain, besides the lactone, an acidic phenol [e.g., bisphenol A (2,2′-bis(4-hydroxyphenyl)propane], becomes weaker on addition of polar solvents. This optochemical sensor system permits detection of the smallest quantities of polar solvents in air [215].

70

Crystal violet lactone can be produced by condensation of Michler's ketone with methyl *m*-diethylaminobenzoate [216]. This

reaction and those involving 5-dimethylaminophthalaldehyde acid [217] and its methyl ester [218] (**71**) are, however, not used in industry. Both compounds **71** can be obtained by formylation of the mixed anhydride of acetic acid and 3-dimethylaminobenzoic acid or of methyl-3-dimethylaminobenzoate, respectively. They can be converted into leuco crystal violet carboxylic acid (**72**).

3-(4-Dimethylaminophenyl)-6-dimethylaminophthalide (**73**) has versatile synthetic possibilities. The phthalide can be produced from 3-dimethylaminobenzoic acid and 4-dimethylaminobenzaldehyde. It can be condensed with dimethylaniline in the presence of aluminum trichloride to give leuco crystal violet carboxylic acid (**72**) [219], which is then converted to crystal violet lactone. A technically simpler variant involves oxidation of the phthalide and subsequent condensation of the 4,4′-bis(dimethylamino)-benzophenone-2-carboxylic acid (**74**) with dimethylaniline to give crystal violet lactone [220]. 3-Nitrobenzenesulfonic acid has proved to be a particularly effective oxidizing agent [221].

Michler's hydrol reacts readily with 3-dimethylaminobenzoic acid and is therefore used for industrial syntheses. The condensation can be carried out in sulfuric [222] or phosphoric acid [223]. Instead of Michler's hydrol, leuco auramine obtained by reduction of auramine with zinc can also be used [224].

If 4-dimethylaminobenzaldehyde, dimethylaniline, and 3-dimethylaminobenzoic acid are reacted in the presence of urea under acidic conditions, the synthesis proceeds via a urea adduct of Michler's hydrol [225]. The reaction gives the 4-dimethylaminobenzylideneurea (**75**), to which dimethylaniline adds to form Michler's hydrol – urea (**76**). The latter can be condensed with 3-dimethylaminobenzoic acid [226].

The leuco crystal violet carboxylic acid formed in the condensation is contaminated by leuco crystal violet. This can be removed by solvent extraction if the carboxylic acid is dissolved in alkali and the solution extracted with a mixture of toluene and heptane, for example [225], [227]. Oxidation of the leuco compound to crystal violet lactone can be carried out in aqueous solution with potassium peroxodisulfate [228] and potassium permanganate [229]. Hydrogen peroxide has proved particularly suitable [230]. The selectivity of oxidation with hydrogen peroxide can be increased by addition of hexacyanoferrate [231]; manganese dioxide [232]; vanadium, chromium, manganese, and iron salts [233]; and copper, cobalt, and nickel salts [237]. Oxidation can also be carried out with oxygen in the presence of salcomine [235] or water-soluble 1,2-cobalt complexes of azo dyes [236].

Besides crystal violet lactone, compounds have also been described that have a methyl group *ortho* to the central carbon atom [237] or in which the amino nitrogen carries a benzyl group [238]. *Lactams* have also been described as color formers [239] and *sulfonephthaleins* (intramolecular sulfonates) as charge-generating compounds for electrophotography [240].

If crystal violet lactone is treated with hydrazine, the *dihydrophthalazinone* (**77**) is formed. This compound has been the subject of extensive investigations.

77

As model experiments with lead tetraacetate have shown, oxidation of the hydrazide leads to loss of nitrogen, followed by rearrangement to several products, which have an absorption maximum at 490 nm [241]. Because of this property the compound is a redox indicator. It is used for colorimetric detection of hydrogen peroxide in metabolic processes [242]. This compound and its derivatives are also used as color formers in electrochromic recording [243].

6.3.3. Betaines and Anionic Dyes

Betaine and anionic triaminotriarylmethane dyes have achieved considerable economic importance. They are derived from pararosaniline dyes containing an aryl or benzyl group with a sulfonic acid group on it.

Arylated pararosaniline dyes with one sulfonic acid group (**78**) are water-insoluble betaines and have pigment character. They are used under the *trade names* Alkali Blue (BASF) and Reflex Blue (Hoechst) to brighten carbon black in printing inks.

78

In 1992, more than 3000 t of this pigment were produced worldwide. *C.I. Pigment Blue 61* (**78**, R = H) (C.I. 42765) and *C.I. Pigment Blue 56* (**78**, R = methyl) (C.I. 42800) are obtained by sulfonation of arylated pararosaniline dyes, whose production is described in Section 6.3.1. *Production Example.* With vigorous stirring, 50 g tri-*m*-tolylpararosaniline is added to 25 g 89 wt % sulfuric acid at 20 – 25 °C over 1 – 2 h. The mixture is heated to 40 – 45 °C and stirred until a sample of three drops is soluble in 20 mL 4 % ammonia on boiling. The reaction mixture is first stirred on 250 g ice and then stirred for 30 min at 50 – 60 °C. The solid is collected by suction filtration and washed with water. The filter cake is suspended in 500 mL water; the suspension is heated to 80 – 85 °C, treated with 27 g 33 wt % aqueous sodium hydroxide solution, and then heated to its boiling point. After ca. 10 min a clear reddish solution is formed, which is treated rapidly with 120 g 12 % sulfuric acid. The mixture is stirred for 5 min at 95 – 100 °C and cooled rapidly with cold water to 80 – 85 °C; the solid is collected by suction filtration and washed with water. After drying at 40 °C, 55 g of the corresponding monosulfonated dye is obtained.

C.I. Pigment Blue 56 can be used to produce printing inks for paper and plastics with high color strength. The properties of the resulting pigment (e.g., purity, color strength, grain hardness, and flushing or flowing behavior) strongly depend on the workup of the sulfonation process and thus on the particle-size distribution obtained. The property profile can also be affected by use of coating agents and other specially selected additives [244], [245].

The three chlorine atoms in 4,4′,4″-trichlorotriphenylmethyl tetrachloroaluminate have differing reactivities. Direct synthesis of the corresponding monosulfonated dye is therefore possible, which makes sulfonation of spirit blue and associated disposal of the sulfuric acid used unnecessary [246]. After sulfanilic acid has been substituted for one chlorine atom the other two chlorine atoms can be replaced by aniline or *m*-toluidine.

C.I. Acid Blue 93. The more highly sulfonated triphenylpararosanilines are readily water soluble and are used for writing inks. This applies particularly to the trisulfonic acid (C.I. Acid Blue 93, C.I. 42780), which is sold by Hoechst under the *trade name* Ink Blue BJT. C.I. Acid Blue 93 can also be produced by condensing formaldehyde with 2 mol equivalents of diphenylaminosulfonic acid and oxidatively coupling the diphenylmethane derivative with another mol equivalent of diphenylaminosulfonic acid in the presence of iron(III) chloride [247].

Although triphenylpararosanilines have achieved importance mainly as betaines, the benzylated pararosanilines are used as anionic dyes for textiles.

C.I. Acid Blue 104 (**79**, R^1 = methyl, R^2 = diethylamino) (C.I. 42735, *trade name* Atlantic Alizarin Walk Blue FFR, Atlantic Industries) gives a clear blue shade on wool. It is obtained by condensation of 4-diethylaminobenzaldehyde with *N*-ethyl-*N*-(3-sulfobenzyl)-*m*-toluidine and oxidation with sodium dichromate and oxalic acid [248].

79

C.I. Acid Violet 49 [*1694-09-3*] (**79**, R^1 = H, R^2 = dimethylamino) (C.I. 42640, *trade name* Atlantic Acid Violet 4BNS, Atlantic Industries). For Acid Violet 49 a synthesis using a diphenylmethanol derivative was developed, which involves four steps without isolation of any intermediates. *N*-Ethyl-*N*-benzylaniline is first converted to the corresponding sulfonic acid, which is then condensed with formaldehyde to give the diaminodiphenylmethane derivative. After oxidation with sodium dichromate, the benzhydrol obtained is condensed with dimethylaniline to give the leuco compound, which is then oxidized to the dye [249].

Production Example. Sulfuric acid monohydrate (520 kg) is charged to a 3-m^3 glass-lined stirred vessel. *N*-Ethyl-*N*-benzylaniline (520 kg) is added slowly with stirring over ca. 20 h at 35 – 40 °C. Then, 520 kg 65 % oleum is added at 35 – 40 °C over 16 h. The reaction mixture is added to 8000 L water with cooling and stirring in a 20-m^3 stirred vessel. The pH is adjusted to 2 – 2.7 by adding of ca. 1850 kg 30 wt % aqueous sodium hydroxide solution within 2 h and keeping the temperature below 60 °C. Next, 135 kg 30 % formaldehyde solution is added and the total volume is made up to 11 000 L with water. The reaction mixture is heated to 95 °C with stirring and kept at this temperature for 4 h. After cooling to 50 – 60 °C the precipitated methane derivative is dissolved at pH 5.6 – 5.8 by adding 400 kg 30 wt % aqueous sodium hydroxide solution. The total volume is made up to 12 000 L with water, and the reaction mixture is divided into three portions. Then, 4000 L of the methane derivative solution is diluted to 13 200 L with water in a 20-m^3 stirred vessel, and 286 kg 35 wt % sodium dichromate solution, 53 kg 78 wt % sulfuric acid, and 200 L water are added at 25 – 30 °C. After 20 min, 51.6 kg *N,N*-dimethylaniline is added at 25 – 30 °C. The reaction mixture is then stirred for 8 h at 25 – 30 °C, 6 h at 45 °C, and 6 h at 75 °C. During this time the leuco compound is formed by condensation and subsequently oxidized to the dye. The total volume is made up to 15 000 L with water, and the dye solution is separated from the chromium sludge by pressing out. The dye is precipitated as a melt at 60 – 70 °C by addition of 850 kg sodium chloride. Then, 1 kg of a nonionic – polymeric emulsifier [castor oil + poly(ethylene oxide)] is added and the stirrer is switched off. The dye resin settles on the bottom of the vessel and is run out onto drying sheets via the bottom valve. Yield: 708 kg.

Oxidation can be carried out with hydrogen peroxide in the presence of a transition-metal catalyst [38] instead of sodium dichromate.

C.I. Acid Violet 17. Another dye used for wool is C.I. Acid Violet 17 [*4129-84-4*] (**79**, R^1 = H, R^2 = diethylamino) (C.I. Food Violet 1, C.I. 42650, *trade name* Hispacid Brilliant Violet S4BF, Robama). This dye can be produced by the same method used for C.I. Acid Violet 49.

Diaminotriphenylmethane dyes, which have easily replaceable substituents in the *p*-position on the third phenyl ring, react with aromatic amines to give triaminotriphenylmethane dyes. If aromatic amines with an alkoxy group *para* to the amino group are used for this reaction, dyes with better lightfastness on wool are obtained. The most commonly used reactive substituents are chlorine and the sulfonic acid group.

C.I. Acid Blue 83 [*6104-59-2*] (**80**, R = H) (C.I. 42660, *trade name* Polar Blue 6 B, CibaGeigy) is produced by condensation of *N*-ethyl-*N*-(3-sulfobenzyl)aniline with 4-

chlorobenzaldehyde, oxidation with dichromate in the presence of oxalic acid, and reaction with *p*-phenetidine in the melt [43].

80

Production Example. A filter cake of *N*-ethyl-*N*-(3-sulfobenzyl)aniline weighing 900 kg, with a dry matter content of 670 kg, is stirred in 800 L water and dissolved by adding 50 kg 45 wt % aqueous sodium hydroxide solution to pH 5. After addition of 175 kg 4-chlorobenzaldehyde, the mixture is heated at 90 °C for 36 h. Excess aldehyde is then removed by steam distillation. The reaction mixture is rendered weakly alkaline by addition of 200 L hot water and 200 kg 45 wt % aqueous sodium hydroxide solution, and the solution is diluted to 6000 L. To each 1000 L of this solution, 600 L ice – water and a solution of 23 kg sodium dichromate in 100 L water are added at 10 °C. A solution of 48 kg oxalic acid and 23 kg 78 % sulfuric acid in 300 L water is added within 5 min. Two oxidation reaction mixtures are combined, heated to 45 °C, and the dye is salted out with sodium sulfate. The dye resin is separated and dried at 95 °C under vacuum. Yield: 950 kg (equivalent to 768 kg chlorine green, 100 %).

To replace the chlorine atom, 600 kg *p*-phenetidine is treated with 475 kg chlorine green (384 kg 100 % dye) in a glass-lined vessel at 70 – 75 °C. The mixture is heated to 100 °C and kept at this temperature for 3 h. The progress of the reaction is followed by TLC. After the reaction is complete, the melt is transferred to a mixture of 6000 L water and 500 kg 30 % hydrochloric acid at 70 °C. The pH of the solution must be between 2 and 3. After stirring for 30 min the precipitated dye resin is allowed to settle and the mother liquor is removed. The resin is washed twice with 1500 L hot water containing some hydrochloric acid. The dye is dissolved in 4000 L water at 80 °C with addition of 30 – 35 kg anhydrous sodium acetate and then salted out slowly by addition of 300 kg sodium chloride. The dye resin is separated and dried under vacuum at 95 °C. Excess *p*-phenetidine is recovered from the acidic wash waters by neutralizing the excess acid and precipitating *p*-phenetidine sulfate with sodium sulfate. *p*-Phenetidine sulfate is collected by suction filtration, converted to the base with sodium hydroxide, and distilled under vacuum. Yield: 465 kg Acid Blue 83, corresponding to 1900 kg commerical product.

C.I. Acid Blue 90 [*6104-58-1*] (**80**, R = methyl) (C.I. 42655, *trade names* Polar Blue G, Ciba-Geigy, Derma Cyanine G, Sandoz) is obtained by replacing a sulfonic acid group by *p*-phenetidine. After condensation of benzaldehyde with *N*-ethyl-*N*-benzylaniline, the product is sulfonated to the trisulfonic acid and oxidized with lead dioxide. The *p*-sulfonic acid group is then replaced by aniline [43]. The dye can be used for wool and leather, and in analysis for detecting proteins [250].

C.I. Acid Blue 13 (**81**) (C.I. 42 571, *trade name* Hispacid Fast Violet 10 B, Robama) is synthesized from Michler's hydrol. Production involves sulfonation of *N*-ethylbenzylaniline and combination of the reaction mixture with a solution obtained by oxidation of bis(4-dimethylaminophenyl)methane with manganese dioxide in sulfuric acid solution. The leuco sulfonic acid is oxidized to the dye with lead dioxide [251].

81

6.4. Hydroxytriphenylmethane Dyes

The simplest members of this series are *benzaurin* [*569-60-8*], a 4-[4-hydroxyphenyl(phenyl)methylene]-2,5-cyclohexadien-1-one, and *aurin* (C.I. 43800), a 4-[bis-(4-hydroxyphenyl)-methylene]-2,5-cyclohexadien-1-one, which contains an additional hydroxyl

group and is also known as *p*-rosolic acid. Benzaurin and aurin are relatively unimportant. Only those dyes with a carboxyl group *ortho* to the hydroxyl group, which can be complexed with metals, in particular chromium, have achieved importance in industry.

Chrome-developing dyes are used mainly in dyeing wool. They can also be used to dye polypropylene materials in the presence of water-soluble metal salts [252].

6.4.1. Metal-Complex Dyes

Hydroxytriarylmethane dyes are best produced by condensation of aromatic aldehydes with *o*-hydroxybenzoic acids and oxidation of the leuco compound formed with nitrosylsulfuric acid in concentrated sulfuric acid. To prevent the introduction of undesired sulfonic acid or nitroso groups under the oxidation conditions, the position *ortho* to the hydroxyl group in the hydroxybenzoic acid must be occupied. Therefore, *o*-cresotic acid [*83-40-9*] (2-hydroxy-3-methylbenzoic acid) is used preferably as starting material.

C.I. Mordant Blue 1 (**82**) (C.I. 43830, *trade name* Diamond Chrome Pure Blue B, Bayer) is obtained by condensing 2,6-dichlorobenzaldehyde with *o*-cresotic acid at 20 – 25 °C in 90 % sulfuric acid. After increasing the acid concentration to 95 %, oxidation is then carried out by addition of sodium nitrite.

82

Production Example. A mixture of 1300 kg sulfuric acid monohydrate and 660 kg 78 wt % sulfuric acid is cooled to 20 – 25 °C in a glass-lined vessel. Then, 200 kg 84 – 90 % 2,6-dichlorobenzaldehyde is added as a moist paste containing 10 – 16 % water, and the reaction mixture is heated to 50 °C to dissolve the reactants completely. It is cooled to 30 °C, small quantities of precipitated resin are removed, and the mixture is cooled further to 15 – 20 °C. Next, 376 kg *o*-cresotic acid (2-hydroxy-3-methylbenzoic acid) is added over 6 h. The mixture is stirred for 12 h at 20 – 25 °C. Neither aldehyde nor cresotic acid should then be detectable in the solution. The sulfuric acid concentration is increased by adding 535 kg sulfuric acid monohydrate; 50 kg sodium nitrite is added at 15 – 20 °C over 6 h. The mixture is stirred for 1 h at 15 – 20 °C, heated rapidly to 60 °C, and stirred at this temperature until the colorimetrically determined color strength no longer increases. The mixture is transferred to 7000 L ice – water, and the precipitated dye is pressed out and washed with water until free of acid. The dye paste is dissolved in 1000 L water with 300 kg 45 wt % sodium hydroxide solution at 85 °C, and the dye is salted out by addition of 500 kg sodium chloride. It is collected by suction filtration and dried at 95 °C under vacuum. Yield: 615 kg, corresponding to 1500 kg commercial product.

C.I. Mordant Blue 1 dyes wool a cherry red shade, which is transformed into a clear pure blue by afterchroming with dichromate. In afterchroming, trivalent chromium is formed by reduction and chelated by the hydroxyl and carboxyl groups. Besides the bathochromic shift, lightfastness is also improved.

Other chrome mordant dyes with useful properties are obtained when benzaldehyde derivatives other than 2,6-dichlorobenzaldehyde are used for the condensation with cresotic acid. *C.I. Mordant Blue 29* (C.I. 43825, *trade name* Chrome Cyanine BLA, Mitsui) is formed with 3-formyl-2,4-dichlorobenzenesulfonic acid, *C.I. Mordant Blue 47* (C.I. 43855, *trade name* Chrome Brilliant Blue GX, Mitsui) with 2,3,6-trichlorobenzaldehyde, and *C.I. Mordant Blue 3* [*3564-18-9*] (C.I. 43820, *trade name* Omegachrome Cyanine GR, Sandoz) with 2-formylbenzenesulfonic acid. *C.I. Mordant Violet 1* (C.I. 43565, *trade name* Omegachrome Violet RC, Sandoz) is obtained from 4-diethylaminobenzaldehyde and cresotic acid.

C.I. Mordant Violet 16 (**83**) (C.I. 43865, *trade name* Omegachrome Violet R, Sandoz). The most successful route for production of **83** involves condensation of 2 mol equivalents of cresotic acid with formaldehyde. The diphenylmethane derivative formed is oxidized to the diphenylmethanol with sodium nitrite. The diphenylmethanol condenses with a third mole

equivalent of cresotic acid to give the leuco dye, which is then oxidized to the dye with sodium nitrite.

83

Production Example. To 4000 kg sulfuric acid monohydrate, 122 kg 40 wt % aqueous formaldehyde solution and 475 kg *o*-cresotic acid are added and stirred for 15 h at 80 °C. The diphenylmethane compound is precipitated by diluting with water to twice the volume. After collection by suction filtration the filter cake is washed with water until neutral and is dried at 90 °C under vacuum. Yield: 92 % methylenedi-*o*-cresotic acid.

Methylenedi-*o*-cresotic acid (177.5 kg) is added to 2250 kg 93 % sulfuric acid at 25 °C in 6 h, and oxidation to the benzhydrol is carried out with 20 kg sodium nitrite at 27 °C over 12 h. The benzhydrol is condensed to the leuco compound by adding 92 kg *o*-cresotic acid and stirring for 12 h at 25 °C. Another 30 kg sodium nitrite is added at 25 – 30 °C over 6 h. After oxidation is complete, 8000 L water and 1000 kg ice are added to the mixture. The dye is precipitated at 8 – 10 °C and pressed out, washed with water until neutral, and dried under vacuum at 95 °C. Yield: 1050 kg commercial product.

Other Uses. Hydroxytriarylmethane dyes sensitize photoconducting zinc oxide layers for electrophotography [253]. Their aluminum complexes have antihalo properties and can be used in filter layers for color photography [254].

6.4.2. Nonionic Derivatives (Triphenylmethanol Derivatives and Lactones)

Phenolphthalein exists in neutral and acid solutions as the colorless lactone (**84**) and in alkali as the red phenolate (**85**) with an absorption maximum at 555 nm.

84

85

It is produced from phthalic anhydride and phenol in the presence of zinc chloride and toluenesulfonyl chloride. A sulfonic acid exchange resin can also be used as the condensation agent in the presence of triphenylphosphite to activate phenol [255].

Lactones derived from 1-hydroxynaphthalene-2-carboxylic acid can be used as filter dyes for instant color photography. The function of the carboxylate group is to form a hydrogen bond to the phenolic OH group and thus increase the pK_a, which determines the pH of the color change. The color is developed in daylight in an alkaline medium and protects the latent image from the nonselective entry of light.

Compound **86** forms a deeply colored dye salt in alkaline media, which becomes colorless when the pH is lowered and thus allows a picture to be reproduced in its true colors [256].

86

Symmetrical and unsymmetrical compounds are produced by condensing formylnaphthoic acid with an ester of 1-hydroxynaphthalene-2-carboxylic acid to give a lactone, which is converted to the intermediate **87** by oxidation and treatment with thionyl chloride.

87

The filter dye is obtained by condensation with hydroxynaphthalene derivatives [257]. Intermediates can also contain acyloxy [258] or halophenoxy groups [259] instead of halogen as the leaving groups.

Tetrahalophenolphthaleins are used together with zinc oxide as photoconducting layers in electrophotography [260].

Phenol red (**88**) (phenolsulfophthalein) is obtained by condensation of *o*-sulfobenzoic acid anhydride with phenol.

88

The corresponding tetrahydroxy compound is produced similarly from catechol [261]. Derivatives of phenolphthalein and phenol red with *halogen* and *alkyl substituents* are indicators that change color between pH 0.5 and 10.6. A thermographic process uses sulfophthalein dyes with volatile amines as salt formers. The action of heat alters the color shade [262]. Octabromosulfophthalein can be used as a sensitizer for zinc oxide photoconductors [263].

Sulfonamides (**89**), which are acylated at the amide nitrogen, can be used as filter and antihalo dyes in color photography. They have intense colors and are deacylated by alkali leading to cyclization involving the central carbon atom and, thus, irreversible decolorization to the sultam (**90**) [264].

89 **90**

The sulfonamides are produced by treating leuco compounds of sulfophthalein, in which the hydroxyl groups are protected, with inorganic acid halides, then introducing the acylamino group, and finally oxidizing to the dye with cleavage of the protecting groups [97].

Hydroxytriphenylmethane dyes are also important in *biomedical analysis*. The monophosphate of phenolphthalein, in which the hydroxyl group is esterified with phosphoric acid, can be used to determine the activity of phosphatases [265]. The phosphate esters are produced from phenolphthalein and phosphorus oxychloride [265]. The monoether obtained from phenol red and galactose can be used for the detection of β-galactosidase [266].

7. Heteroaryldiarylmethane and Diheteroarylarylmethane Dyes

The aromatic rings in triarylmethane dyes can be replaced by one or two heterocycles. Examples are aniline derivatives, in which the nitrogen forms part of a heterocycle that is condensed to the phenyl ring *ortho* to the nitrogen to give a saturated five- or six-membered ring. However, indoles and carbazoles with unsaturated rings have proved particularly useful.

7.1. Cationic Dyes

7.1.1. Monoaminodiphenylheteroarylmethane Dyes

By condensation of aminobenzophenones with indole derivatives, dyes are obtained that dye polyacrylonitrile fibers blue, green, and black. Dyes containing phenylamino groups give dyeings with particularly good lightfastness [267]. The dyes can also be produced by oxidation of the corresponding leuco compounds with lead dioxide, sodium dichromate, iron(III) chloride [268], or oxygen [23], [188] in the presence of chloranil and iron or cobalt complexes. The substitution pattern of the second phenyl group has a considerable effect on the color shade. The introduction of chlorine *ortho* to the central carbon atom gives rise to a blue shift for steric reasons. A methoxy group in the *para*-position gives black color shades [3, pp. 381, 406 – 408].

7.1.2. Diaminodiphenylheteroarylmethane Dyes

Cationic dyes in this series are obtained by condensation of 4,4′-diaminobenzophenone and

its derivatives with α-substituted indoles [269]. The amino groups can also be introduced later into the dye skeleton by first condensing 4,4′-dichlorobenzophenone with an α-substituted indole and then replacing the *p*-chlorine atom with an amino group. Both aromatic amines (e.g., *o*-phenetidine [270]) and aliphatic ones (e.g., morpholine) can be used for this reaction. In the latter case the substitution reaction is carried out in the presence of aluminum trichloride [271].

7.2. Nonionic Derivatives (Triphenylmethanol Derivatives, Lactones, and Leuco Compounds)

Lactones. The reaction of phthalic anhydride with 2 mol equivalents of 1-ethyl-2-methylindole gives a *bisindolylphthalide* [*22091-92-5*] (**91**), which is an effective red color former for pressure-sensitive paper [272].

91

Phthalic anhydride can be reacted with 1-ethyl-2,2,4-trimethyl-1,2,3,4-tetrahydroquinoline to yield a green color former (**92**) [273].

92

Color formers containing only *one heterocyclic ring* (**93**) are derived from substituted 2-(4-aminobenzoyl)benzoic acids, which are condensed with indole derivatives [274].

93

Color formers that contain a dimethylaminophenyl [275] or nitrophenyl ring [276], or a naphthalene group [277] instead of the phenyl ring, have been described as well.

Lactones containing heterocycles can also be obtained by using heterocyclic anhydrides instead of phthalic anhydride. Pyridinedicarboxylic acid anhydride can be reacted with aniline derivatives [278] and with equimolar quantities of an aniline and a heterocyclized aniline derivative [279] or an indole derivative [280], [281] to form an azaphthalide. Isomerically pure 4-azaphthalides containing indoles (**94**) are blue color formers, which do not exhibit self-coloration and are superior in lightfastness to crystal violet lactone [282].

94

Lactones are also formed with pyrazine [283] and quinoxaline dicarboxylic acid anhydrides [284], which are obtained by condensation with 2 mol equivalents of an aniline derivative or contain an indole derivative besides an aniline derivative.

Ethers. Color formers based on a new principle are the chromenoazaindolizines (**95**) [285] and chromenothiazoles (**96**) [286].

95

96

The chromenoazaindolizines are produced by reacting a 2-hydroxyphenacyl halide with 2-aminopyridine and condensing the *o*-hydroxyphenylazaindolizine with Michler's hydrol. After oxidation and addition of alkali, the phenolate oxygen attacks the central carbon atom to form a six-membered ring via an ether bridge. Chromenothiazoles can be obtained by the same reaction sequence. Instead of 2-aminopyridine, an *N,N*-dialkylthiourea is used and the 2-amino-4-(2-hydroxyphenyl)thiazole formed is used as starting material for the color former.

Leuco Compounds. Some leuco compounds are oxidized by air on acidic self-duplicating paper to give intense colors. Heterocycles play an important role in the synthesis of these dyes. Condensation of benzaldehyde derivatives with indole derivatives gives red color formers (**97**).

97

Heterocyclic aldehydes, such as 3-indolecarbaldehyde, furfural, 4-pyridinecarbaldehyde, and 2-pyrrolecarbaldehyde have also been used with success. The aniline derivatives give green and the indole derivatives red color formers [287].

Leuco bases of the diaminodiphenylindolylmethane dyes [288] have been proposed as color formers for heat-sensitive recordings, and those of the diaminodiphenylpyridylmethane dyes as electrochromic material [289]. 4-Aminophenyl-4′-alkoxyphenylindolylmethanes give a deep black coloration in air [290].

Of the heterocyclic aldehydes, *carbazolecarbaldehyde* is particularly important. Condensation of *N*-ethyl-3-carbazolecarbaldehyde with 2 mol equivalents of *N*-methyldiphenylamine gives a leuco compound (**98**) that turns blue on oxidation [291].

98

This compound belongs to the group of *secondary color formers*. Because of the necessary oxidation, its color develops slowly. However, for this reason, it is an ideal supplement to some primary color formers such as crystal violet lactone, whose colors develop immediately and then become weaker after a certain period. The combination of primary and secondary color formers gives optimum lightfastness. Color formers containing benzoannelated carbazoles [292] or two carbazole groups besides an aniline substituent [293] have also been described.

Leuco compounds obtained by condensing heterocyclic aldehydes with aniline derivatives are readily oxidized in the presence of peroxidase and can therefore be used to detect hydrogen peroxide [294].

8. Dyes with Several Chromophores

These dyes contain two or more triarylmethane chromophores or are polymeric. The triarylmethane chromophore can also be bonded to that of azo and oxazine dyes.

8.1. Bis(triarylmethane) Dyes

Condensation of terephthalaldehyde with aromatic amines in the presence of an acidic catalyst and subsequent oxidation gives dyes (**99**) in which the malachite green chromophore is bonded to that of Michler's hydrol blue. They can be used to dye or tint cotton, silk, leather, and paper [295].

99

Bis(triaminotriphenylmethane) dyes are produced from 4,4′-diaminodiphenylmethane derivatives and bridged dianilines and subsequent oxidation with oxygen in the presence of (dihydrodibenzotetraaza[14]annulene)iron or -cobalt and chloranil as catalysts [296], [297]. Reaction of *N*-ethyl-*m*-toluidine with *p*-xylylene dichloride gives a dianiline, from which dye **100** is obtained. This dye has a very high affinity for wood-free paper and colors bleached sulfite pulp blue with a red cast.

Production Example [298]. A mixture of 508 parts 4,4′-methylenebis(*N,N*-dimethylaniline), 372 parts *N,N′*-diethyl-*N,N′*-di-3-tolyl-*p*-xylylenediamine, 1200 parts glacial acetic acid, 300 parts 1,2-propanediol, 10 parts chloranil, and 10 parts (dihydrodibenzotetraaza[14]annulene)iron is oxidized at 35 – 45 °C by passing through air with vigorous stirring until oxygen consumption can no longer be detected. Approximately 2400 parts of an ca. 45 % solution of the dye (**100**) are obtained.

Uses. Dimeric diaminotriphenylmethanes (leuco bases) can be used as photoconductors [136] and, in combination with quinones, for ink jet printing [294] and thermographic [299] recording materials.

8.2. Oligomeric and Polymeric Triarylmethane Dyes

Oligomeric and polymeric triarylmethane dyes are produced by treating formaldehyde with *N,N′*-ethylenebis(*N*-ethylaniline) in acetic acid solution, adding dimethylaniline, and oxidizing with oxygen in the presence of chloranil and (dihydrodibenzotetraaza[14]annulene)iron [300].

Polymeric triarylmethane dyes with a polyester, polycarbonate, polyurethane, or polyethylenimine chain as the backbone are also known [301]. A dye with a polyester chain can be produced from 4-dimethylaminobenzophenone, phosphorus oxychloride and the polymeric aniline **101**. The latter is made from *N,N*-di(2-hydroxyethyl)-3-methylaniline and terephthaloyl chloride.

101

Triarylmethane dyes, which are bonded to bisphenol A diglycidyl ether via two secondary amino groups, are polycationic polymers that can be used as starting materials for the production of optical, electronic, photoelectronic, or electrochemical devices, films, or coatings [302]. Oligomeric and polymeric triarylmethanes (leuco bases) can be used as charge-transfer compounds in electrographic photoconductors [303].

100

8.3. Triarylmethane Dyes with Other Chromophores

By coupling a triarylmethane dye with a salicylic acid derivative, an additional group that is capable of complexing metal ions is introduced. This type of dye can be produced by diazotizing 5-amino-2-chlorobenzaldehyde and coupling the product with *o*-cresotic acid. The formylazo compound thus obtained is condensed with 2 mol equivalents of *o*-cresotic acid in sulfuric acid, and the product is oxidized with nitrosylsulfuric acid [304]. Azodiaminotriphenylmethane dyes have been recommended as additives for galvanizing baths for copper plating [305].

By condensation of Michler's hydrol with oxazine dyes (which contain only one amino group and therefore have a hydrogen atom *para* to the azine nitrogen that can be replaced) followed by oxidation, biscationic dyes are obtained. These contain the diphenylmethane and oxazine systems as chromophores [306].

9. Acridine Dyes

Acridine dyes are alkyl derivatives of 3,6-diaminoacridine (**102**), 9-(4′-aminophenyl)-3-aminoacridine (**103a**), and 9-(4′-aminophenyl)-3,6-diaminoacridine (**103b**). Compound **103a** is identical to the oldest acridine dye, *chrysaniline,* discoverd by A. W. HOFMANN as a byproduct in the fuchsin synthesis.

102

103a: R = H
103b: R = NH_2

Acridine dyes have low lightfastness and are not commercially important. They were formerly used for printing on tanned cotton because of their heat resistance. Their use as charge stabilizers [307], [308] and light-sensitive materials in electrophotography [309] has been described.

Acridine dyes derived from **102** are not synthesized from the acridines, but from 1,3-diaminobenzenes and aliphatic or aromatic aldehydes. The tetraaminodiarylmethane derivatives first formed eliminate ammonia to give leuco acridines. The latter are readily oxidized with atmospheric oxygen or iron(III) chloride to give acridine dyes. With acid, the dyes form salts that can give yellow, red, and brown shades. *Acridine yellow*, the 2,7-dimethyl derivative of **102**, is obtained in this way from 1,3-diamino-4-methylbenzene and formaldehyde. Other examples are *acridine orange 2 G* [*65-61-2*] (**104**) [C.I. Basic Orange 14, C.I. 46005, derivative: C.I. Solvent Orange 15 (free base)] and *euchrysin GGNX* [*4215-95-6*] (**105**) (C.I. Basic Yellow 9, C.I. 46040). The latter is produced from 1,3-diamino-4-methylbenzene and acetaldehyde with ring closure and subsequent oxidation by iron(III) chloride [310].

104

105

Acridine orange 2 G (zinc chloride double salt) can also be obtained by reduction of bis-(4-dialkylamino-2-nitrophenyl)methane with zinc in hydrochloric acid [311].

10. Xanthene Dyes

If the carbon atoms *ortho* to the central carbon in di- and triarylmethane dyes are bonded via an oxygen atom, xanthene dyes are obtained. Incorporation of this bridge has a pronounced hypsochromic effect. Although green and blue dominate in the triphenylmethane series, the characteristic color shade of xanthene dyes is red.

The xanthene dyes are classified according to the substituents in the 3- and 6-positions. Mono- and diaminoxanthenes and hydroxyxanthenes are important classes of dyes.

10.1. Ring-Closed Diphenylmethane Dyes (Pyronins)

Pyronin G and Pyronin B. The most widely used pyronin dyes are pyronin G [*92-32-0*] (**106**, R = methyl, C.I. 45005) and pyronin B [*2150-48-3*] (**106**, R = ethyl, C.I. 45010).

106

For both dyes, formation of the oxygen bridge occurs at the leuco stage. The leuco compound is obtained by condensation of formaldehyde with 3-dimethyl- or 3-diethylaminophenol. For pyronin G, nitrous acid has proved the best oxidizing agent and, for pyronin B, iron(III) chloride. Isopentyl nitrite has been recommended as oxidant for the production of particularly pure pyronin G [312].

Both dyes exist as the dye salt or the hydrol, depending on pH. The equilibrium position and distribution of the dye between water and hydrophobic solvents have been thoroughly investigated [313].

Uses. Pyronins G and B can be used for the quantitative determination of metals. Some metals form tetra- or hexavalent complex anions with halides, which combine with the dye cations to form ion pairs. These can be extracted from aqueous solutions with hydrophobic solvents and determined by visible spectroscopy. Complex anions that can be analyzed quantitatively by this method are $TlCl_4^-$ [314], $PdBr_4^{2-}$ [315], HgI_4^{2-} [316], PtI_6^{2-} [317], CdI_4^{2-} [318], TaF_6^- [319], and BF_4^- [320]. Sulfur dioxide [321] and carbon monoxide [322] can also be determined quantitatively through ion-pair formation. After reduction of $NaIO_3$ by CO or SO_2 in the presence of chloride ions, the complex anion ICl_4^- is formed in a quantity equimolar to that of SO_2 and CO. The ion pairs formed with pyronin G can be extracted with benzene.

Pyronin G has a higher affinity for RNA than for DNA [323], [324]. The selective coloration of RNA by pyronin G offers the possibility of determining the activity of ribonucleases and of following them spectroscopically [325].

Pyronins with heteropolyacids as the anion become positively charged through friction and can be used as pigments and charge stabilizers for toners in electrophotography [308].

Pyronins react with alkali cyanides, initially giving leuco compounds with a nitrile group in the 9-position. Oxidation gives blue cyano-substituted xanthene dyes (**107**), which can be used for dyeing cotton, silk [326], and polyacrylonitrile fibers [327].

107

Both pyronins and their cyano-substituted derivatives are suitable as laser dyes [328]. How rapidly the photodegradation of xanthene nitriles occurs in various solvents and which mechanism predominates have been investigated spectroscopically [329].

Rhodamine S (**108**) (Basic Red 11, C.I. 45050) is obtained from 3-dimethylaminophenol and succinic anhydride [330].

108

10.2. Ring-Closed Triphenylmethane Dyes

Unlike the pyronins, some dyes contain a third phenyl ring. This can be introduced via the aldehyde moiety, whereby leuco compounds are formed, which must then be oxidized. With phthalic anhydride, *o*-sulfobenzoic acid anhydride, or benzotrichloride, the dye is obtained directly.

10.2.1. Monoaminoxanthene Dyes

Monoaminoxanthene dyes, which have a carboxyl group *ortho* to the central carbon atom, exist as lactones and are widely used as color formers. The corresponding cationic dyes have not achieved any economic importance.

10.2.1.1. Cationic Dyes

Cationic monoaminoxanthene dyes are derived from the corresponding lactones, which are obtained by condensing 2-(4-dialkylamino-2-hydroxybenzoyl)benzoic acids with phenols (see Section 10.2.1.2). Conversion to a permanent cationically charged state involves conversion of the carboxyl into an amide [331] or an ester group. With β-naphthol a red dye (**109**) [332] is obtained and with *p*-diethylaminophenol a green dye (**110**) [333].

109

110

10.2.1.2. Fluorans

Fluorans are classed as xanthene lactones. They are spiro compounds in which a xanthene group is bonded to a benzofuranone moiety. These compounds have gained a strong position in the market because of their chromogenic behavior and the possibility that fluorans can be prepared in almost all colors, depending on the type of substitution.

Fluorans are used in the paper industry as color formers and are the color-forming components of self-duplicating and thermofax paper. Consumption is distributed approximately equally between the two applications and is estimated to be ca. 5000 t total. Self-duplicating paper has extensively replaced carbon paper and is now used for almost all forms. For production of self-duplicating paper, microdrops that contain solutions of the color former in liquid hydrocarbons are coated with a polymer layer to form microcapsules. The underside of a transmitting paper is coated with these microcapsules. When this paper is written on, the capsules break under the pressure and the color former is transferred to the upper side of the receiver paper, which is to provide the copy, and produces a color reaction with an acidic substance that coats the upper side of that paper. This acidic substance can be an inorganic material, such as bentonite or montmorillonite, or an organic such as a *p*-alkyl- or *p*-phenylphenol – formaldehyde polycondensate or an alkyl-substituted zinc salicylate.

Red and Orange Color Formers. *3-Diethylamino-7,8-benzofluoran* [*26628-47-7*] (**111**) is a lactone that becomes red on the action of acid and has practical applications.

111

According to a patent published in 1985, homologues have been synthesized with an isobutyl or isopentyl group on the amino nitrogen [334].

In 1966, Fuji reported that condensation of 2-(4-diethylamino-2-hydroxybenzoyl)-benzoic acid with 2,4-dimethylphenol gives a colorless lactone, *3-diethylamino-4,6-dimethylfluoran* [*21934-68-9*] (**112**), which turns orange through the action of acid and can be used as a color former [335].

112

Other 2,4-disubstituted phenols were later used to produce fluorans [336]. Color formers giving orange and red dyes are 3-*N*-isobutylethylamino-7-chlorofluoran [334], 3-*N*-di-*n*-butylamino-6-methyl-7-bromofluoran [337], and fluorans with a phthalimido group in the 7-position [338].

Selective replacement of a chlorine atom in fluorescein chloride with cyclohexylamine or

another primary amine has also been used to synthesize fluorans [339].

The color former 3-cyclohexylamino-6-chlorofluoran [*26206-78-0*] (**113**) has useful technical properties attributed to the secondary amino group and thus to its reduced base paper coloration.

113

Green Color Formers. In 1967, Fuji discovered that fluorans with alkylamino groups in the 3- and 7-positions are green color formers. They can be obtained by condensation of 2-(4-diethylamino-2-hydroxybenzoyl)benzoic acid with a *p*-aminophenol derivative [340]. With *n*-dodecylamino-*p*-anisidine as the *p*-aminophenol derivative, *3-diethylamino-7-n-dodecylaminofluoran* (**114**) is obtained [341]. This color former is readily soluble in hydrophobic solvents. *3-Diethylamino-7-dibenzylaminofluoran* [*34372-72-0*] (**115**) has important practical applications [342].

114

115

The color former becomes green on acidification. It is produced by reaction of 3-diethylamino-7-aminofluoran with benzyl chloride in a mixture of toluene and water in the presence of potassium carbonate. Benzyl *p*-toluenesulfonate can be used instead of benzyl chloride [343].

Black Color Formers. If 4-hydroxydiphenylamine is used for the condensation, 3-diethylamino-7-anilinofluoran, a black-green color former, is produced [344]. 3-Di-*n*-butylamino-7-*o*-chloroanilinofluoran [*85639-01-6*] (**116**) is an almost neutral black color former [345].

116

The aim of color former development has always been to produce black copies that can also be photocopied well. Initially, this could be achieved only by combining several color formers of different colors. Mixtures of orange, red, green, and violet give black. These mixtures are still the basis of self-duplicating paper with mineral clays as the acid component. In 1969, NCR found that fluorans with a methyl group in the 6-position are neutral black color formers [346].

3-Diethylamino-6-methyl-7-anilinofluoran. 3-Diethylamino-6-methyl-7-aminofluoran was arylated with 2-bromobenzoic acid and the product subsequently decarboxylated. The 3-diethylamino-6-methyl-7-anilinofluoran [*29512-49-0*] (**117**) obtained is black and has good application properties. Industrial production has been achieved by development of an economical synthesis of 2-methyl-4-methoxydiphenylamine [347].

117

Synthesis of the color former itself is carried out in concentrated sulfuric acid. After condensation of 2-(4-diethylamino-2-hydroxybenzoyl)benzoic acid with 2-methyl-4-methoxydiphenylamine, a phthalide is formed with a hydroxyl and a methoxy group *ortho* to the central carbon atom. This phthalide cyclizes in alkali with loss of methanol to give the fluoran (**117**) [348]. Instead of 2-methyl-4-methoxydiphenylamine,

its *N*-formyl derivative can also be used. The formyl group is eliminated by hydrolysis of the phthalide before cyclization to the fluoran [349]. This color former is still important economically and is marketed worldwide by a number of suppliers.

Fluorans with a *pyrrolidine group* [350], [351] or an *N-methylcyclohexylamino group* [*55250-84-5*] [350] in the 3-position have similarly useful properties. Compounds with *N*-alkylarylamino groups in the 3-position [352] and aniline derivatives with an alkylated benzene ring in the 7-position [353], [354] have also been synthesized.

The black fluoran color formers are particularly useful in combination with organic developers. Whereas insufficient lightfastness was achieved with acidic or acidically modified clays, a neutral black with good fastness could be formed by using developers based on phenolic resin.

Fluorans for Thermoreactive Papers. The discovery that fluorans can also be used to produce thermoreactive paper opened up new possibilities. Incorporation of a fluoran and, for example, bisphenol A in a binder [e.g., poly(vinyl alcohol)] gives a colorless substance that forms a dye when heated [355]. The action of heat melts the thermoreactive substance, thus exposing the color former to the acidic phenol. No microcapsules are required for the production of thermoreactive paper. The starting materials are incorporated into the binder in finely ground form and applied to the carrier paper in a thin layer.

The first thermoreactive papers contained 3-diethylamino-6-methyl-7-anilinofluoran as the color former. After extensive optimization experiments, thermoreactive fax paper was produced, which satisfied most requirements. The solubility of the color former in the binder, though low, and its undesired reaction with phenol in the cold were disadvantages that made the production of pure white paper difficult. Further product development was aimed at fluorans with lower solubility in the binder. Derivatives with a *N*-ethyltetrahydrofurfurylamino group [*102232-11-1*] [356] and particularly an di-*n*-butylamino group [*89331-94-2*] (**119**) [358] in the 3-position, instead of the diethylamino group, have proved successful.

118

119

In the search for optimized products, fluorans have also been produced that have *N*-ethylisobutylamino [359], *N*-isobutylalkoxyalkylamino[360], *N*-propylcyclohexylamino[361], diarylamino [362], and 3,5,5-trimethylhexahydroazepinyl groups [363] in the 3-position. Phenylethyl [364], pyridyl-2-ethyl [365], and alkyl groups with more than nine carbon atoms [366] have also been introduced as substituents. New compounds have likewise been obtained by reductive alkylation of the amino group with ketones [367].

Fluorans which absorb in the IR region and can therefore be used for printing bar codes contain a polyanilino group in the 3-position [368]. Other fluorans have been obtained by introducing a methyl [369] or an ethoxypropyl group [370] in the 2-position and by replacing the 6-methyl group with phenyl, benzyl [371], halogen [372], and methoxy groups [373].

The anilino group in the 7-position has also been modified. It has been substituted by lower alkyl groups [353], [374] and by C_5 to C_8 alkyl groups [354] in the *p*-position and by a 1-naphthylamino group [375]. Alkyl groups can be introduced into the color former molecule by reaction with secondary and tertiary alcohols [376]. Substitution with ketones has led to *fluoran dimers* [377], [378]. Fluoran dimers can also be produced by using methylenebisphthalic acid anhydride as the starting material [379]. *tert*-Butyl [380], alkoxy or aryloxy [381], carboxyl, and alkoxycarbonyl groups [382] have also been described as substituents on the benzofuranone part of the molecule.

10.2.2. Diaminoxanthene Dyes

Rhodamine dyes are the most important diaminoxanthene dyes. They are xanthenes that contain a 2-carboxyphenyl ring on the central carbon atom. Diaminoxanthene dyes are unimportant in dyeing textiles because their lightfastness is usually insufficient. They are used mainly to dye paper and, after precipitation with heteropolyacids, to produce printing inks. Ca. 2000 t of rhodamine dyes are produced and processed annually.

10.2.2.1. Cationic Dyes

Symmetrical rhodamine dyes are obtained in a melt reaction, in which 2 mol equivalents of a 3-aminophenol are condensed with 1 mol equivalent of phthalic anhydride at ca. 180 °C. Unsymmetrical dyes are produced from a 2-(4-dialkylamino-2-hydroxybenzoyl)benzoic acid, which can be obtained by reacting equimolar quantities of a 3-dialkylaminophenol with phthalic anhydride in nonpolar solvents such as xylene or toluene. The benzoylbenzoic acid is condensed with another 3-dialkylaminophenol in concentrated sulfuric acid at ca. 50 °C [383].

Rhodamine B [*81-88-9*] (**120**) (C.I. Basic Violet 10, C.I. Solvent Red 49, C.I. 45170, BASF) is obtained by melting 3-diethylaminophenol with phthalic anhydride at 170 – 180 °C [384]. If the reaction is carried out in *o*-dichlorobenzene, the dye can be obtained in particularly pure form [385].

120

The dye is readily soluble in water and gives a blueish red coloration. It is characterized by its intense fluorescence.

The ethyl ester of rhodamine B (Rhodamine 3 B, C.I. Basic Violet 11, C.I. 45175) is obtained by treating rhodamine B with diethyl sulfate in the presence of base in aprotic solvents such as butyrolactone [386].

Because of their high solubility the *hydroxyethyl esters* (rhodamine 2 BU) are particularly suitable for the preparation of liquid formulations. They are obtained by reacting rhodamine B with a dialkyl sulfate in glycol and subsequent heating, whereby transesterification with the solvent glycol takes place [387]. For the production of red ballpoint pastes, esters of *long-chain alcohols*, such as nonanol, have been developed [388].

Rhodamine 2 C base is produced from 3-ethylamino-4-methylphenol and phthalic anhydride in a melt reaction. The dye is red with a yellow cast, but is unimportant because of its poor water solubility. However, the esters of rhodamine 2 C base are readily water soluble and even allow the preparation of liquid formulations [389].

Rhodamine 6 G [*3056-93-7*] (**121**) (C.I. Basic Red 1, C.I. 45160, BASF) is the ethyl ester of rhodamine 2 C base. It is obtained by esterification with diethyl sulfate.

121

Production Example. Stepwise, 600 kg 3-ethylamino-4-methylphenol and then 1016 kg phthalic anhydride are added to 3310 kg *o*-dichlorobenzene in an 8100-L titanium-lined steel vessel. The temperature is raised to 177 – 180 °C within 2 – 3 h, and the mixture is stirred at this temperature until condensation is complete (6 h). After cooling to 100 °C, 2080 L water is added, and a mixture of water and *o*-dichlorobenzene is distilled off. For complete removal of the *o*-dichlorobenzene, another 1100 L water is added during distillation over 3 – 4 h. When all the *o*-dichlorobenzene has been removed, water is added until the vessel is filled to 3/4. Then, 1820 kg 30 wt % aqueous sodium hydroxide solution is added over 1 h. The mixture is heated to 85 – 90 °C, and the pH is adjusted to 12 by addition of 20 kg 30 wt % aqueous sodium hydroxide solution. After stirring for 4 h at 85 – 90 °C,

the base is allowed to settle and the aqueous phase is decanted. After addition of water and 154 kg sodium hydroxide as a 30 % solution, the mixture is heated again to 85 – 90 °C for 2 h to completely hydrolyze the phthalic acid complex. Rhodamine 6 G base is then isolated and washed with warm water at 40 – 45 °C until the alkali is completely removed.

After 2950 kg *o*-dichlorobenzene has been charged to a 7500-L titanium-lined steel vessel, 1020 kg rhodamine 6 G base is added as a moist filter cake. The temperature is raised slowly to 95 – 110 °C until water begins to distill. The temperature is increased to 140 °C over 3 – 4 h and then kept at 155 – 160 °C for 0.5 h to completely remove water. Next, 605 kg diethyl sulfate is added at 155 – 160 °C over 10 h. The mixture is stirred for 4 h at this temperature and then cooled to 100 °C. After addition of 2840 L water, *o*-dichlorobenzene is distilled off, and 1135 L water is added during the distillation. After 7 – 8 h the removal of *o*-dichlorobenzene is complete. The pH of the solution is 2 – 3 as a result of the hydrolysis of excess diethyl sulfate. The reaction mixture is transferred to a 26 000-L stirred tank and diluted to 23 000 L with water. Then, 54 kg sodium acetate is added at 75 – 80 °C, and the pH is adjusted to 4 with 180 kg sodium hydrogencarbonate. After addition of clarifying agents the solution is filtered at 75 – 80 °C through a press and the filtrate is divided into two parts. To each part, 680 kg 30 % hydrochloric acid is added, and the dye is salted out with 3 % sodium chloride at 40 °C. After stirring for several hours, rhodamine 6 G is isolated by suction filtration at 35 – 40 °C and the dye is dried at 85 –90 °C. Yield: 1020 kg rhodamine 6 G.

The dye can also be isolated as a granulate if precipitation is carried out at high temperature and the droplets formed solidify to solid spheres on cooling [390].

With heteropolyacids, water-insoluble rhodamine dyes can be precipitated; these are used as pigments in the printing industry. Phosphomolybdotungstic acid has proved particularly effective. If precipitation is carried out in the presence of special amines [391], pigments are obtained with optimum color strength, brilliance, and good dispersibility.

If rhodamine 2 C base is treated with phosphorus oxychloride and then with a primary amine, surprisingly no amide or lactam is formed but a dimeric imide in which the amine nitrogen forms a bridge between the carboxyl groups of two dye molecules. If an additional basic group is introduced via the amine, as in *N,N*-dimethylpropylenediamine, dyes are obtained that have a high affinity for paper [392].

When *N*-aryl-substituted rhodamine dyes are reacted with formaldehyde and an imidazole derivative, basic groups in the form of an imidazolylmethyl group are introduced, also giving dyes with a high affinity for paper [393].

Rhodamine dyes with polyoxyalkylene groups on the nitrogen have a fugitive character. They do not adhere to textiles or human skin and are therefore particularly suitable for marking fibers and yarns in the production of woven fabrics and tufting articles because the marks can later be removed [394].

Because of their brilliance, rhodamine dyes can also be used in *electrophotography*. They can be processed to give red toners, which – together with yellow and blue toners – allow the production of colored photocopies. Dyes with tetrafluoroborate [395] and the anions of heteropolyacids [396] and trifluoromethanesulfonic acid [397] are particularly useful.

Rhodamine dyes with two carboxyl groups are obtained by treating 3-aminophenols with 1,2,4-benzenetricarboxylic acid anhydride. They are used for fluorescent labeling of nucleotides in chain termination DNA sequencing procedures [398].

Laser Dyes. Because of their high quantum yield, rhodamine dyes can be used as laser dyes (→Laser Dyes, Chap. 2.4.) [399]. When the mobility of the *N*-alkyl groups is hindered by bonding to the benzene ring, the quantum yield is high [400]. This applies particularly to dyes based on *julolidin* (**122**) [401].

122

In the search for laser dyes with enhanced photostability, products have been synthesized with 2,2,2-trifluoroethyl substituents on the nitrogen atoms [402].

Aryl-substituted diaminoxanthene dyes give a coloration that is shifted to the blue range compared to those with alkyl substituents. Aryl-substituted dyes can be obtained by treating benzotrichloride with resorcinol [45] and replacing the chlorine atoms in 3,6-dichloro-9-phenylxanthylium chloride with aromatic amines [403]. Because of steric hindrance, red with only a slightly blue cast is obtained with 2,6-dimethylaniline. Aryl-substituted rhodamine dyes can also be obtained from phthalic anhydride and aryl-substituted 3-aminophenols [332], [404].

10.2.2.2. Nonionic Derivatives (Lactones and Related Compounds)

Lactones. Depending on the pH and the nature of the solvent, *rhodamine B* exists either as a cation, a zwitterion, or a colorless lactone. In protic solvents, the equilibrium position between the zwitterion and the lactone is influenced by hydrogen bonds and by the dielectric constant and polarizability of the solvent. In aprotic solvents, depending on the acidity only the lactone or the cation can be detected [405].

Isolating the pure, colorless lactone of rhodamine B is difficult. The equilibrium with the cationic dye can be shifted in the direction of the lactone, however, if the amine nitrogens of the xanthene dye carry phenyl substituents. Thus, tetrachlorophthalic anhydride and 3-hydroxy-*N*-methyldiphenylamine give a colorless compound (**123**) that becomes purple blue on acidic clay [406].

123

Lactones of diaminoxanthenes with two aryl groups on one or both nitrogens are also suitable as color formers [407]. The bis(diphenylamino)xanthenes can be obtained by phenylation of bis(monophenylamino)xanthenes with iodobenzene or by treating 3-hydroxytriphenylamine with phthalic anhydride [408]. They develop a blue color on acidic clays.

Valuable red color formers (**124**) are derived from 2,4-bisazarhodamine dyes. They lactonize to colorless compounds and can be produced by condensation of 2-(4-diethylamino-2-hydroxybenzoyl)benzoic acid with, e.g., 2-dibutylamino-6-methylpyrimid-4-one [409].

124

Lactams. Unlike most lactones, rhodamine lactams are stable compounds. The equilibrum can be shifted in the direction of the dye when aryl groups with electron-withdrawing substituents are present in the molecule. One of the first color formers, with which two-color effects were achieved together with crystal violet lactone, was the lactam (**125**) [*29199-09-5*] obtained from rhodamine B and 4-nitroaniline. It was described in 1955 by NCR [410].

125

Thio- and dithiolactones are colorless. They are obtained from rhodamine B and phosphorus pentasulfide. The thiolactone ring can be opened only in the presence of Lewis acids [411].

Sultams have an even lower tendency to color formation than lactams. Sultams are derived from sulfonamides of primary amines and are formed by attack of the amide nitrogen on the central carbon atom with loss of a proton. The sultam ring can be forced to open only if

the amide nitrogen can be substituted in an intramolecular reaction. This is the case with sultams in which the amide nitrogen has been arylalkylated with bivalent compounds such as 1,8-bis(bromomethyl)naphthalene compound (**126**) [412] or pentafluorophenacyl bromide [413]. At higher temperature the amide nitrogen is arylalkylated or arylated to form a six- or five-membered ring, thus liberating the color chromophore (**127**).

126 **127**

Sultams in which one amino group of an *o*-phenylenediamine is part of the sultam ring and the second amino group has been acylated with phenyl chloroformate (**128**) also cleave to form a dye at elevated temperature. The driving force is further acylation of the amide nitrogen, with loss of phenol and formation of a benzimidazolone (**129**) [414].

128 **129**

Whereas sultams with bivalent substituents liberate a dye in a thermal reaction, some xanthenes can undergo fragmentation in a thermally induced reaction that results in the opposite effect (i.e., a negative image). Suitable compounds for this application are xanthenes that have a sulfonamide group *ortho* to the central carbon atom and in which the nitrogen carries a methyl and a *tert*-butoxycarbonyl group. At elevated temperature, *tert*-butyl alcohol and car-bon dioxide are liberated and the *N*-methylsulfonamide cyclizes to the colorless sultam [415].

Sulfonamides of xanthene dyes that have an alkyl and an acyl group on the amide nitrogen (**130**) are readily deacylated with alkali and cyclize to colorless sultams (**131**). They are therefore valuable correction filter and antihalation dyes in photographic materials. During illumination, they contribute to a sharp image with accurate colors and can be completely bleached out during development [416].

130 **131**

10.2.2.3. Anionic Dyes

Sulforhodamine B [*3520-42-1*] (**132**) (C.I. Acid Red 52, C.I. 45100, *trade name*: Duasyn Acid Rhodamine B 01, Hoechst), the first anionic xanthene dye, was synthesized by STEINER in 1906. This dye is produced by condensation of 2 mol equivalents of 3-diethylaminophenol with 1 mol equivalent of 4-formyl-1,3-benzenedisulfonic acid in sulfuric acid solution to give the leuco triphenylmethanedisulfonic acid. Heating in 90 % sulfuric acid to 135 °C causes dehydration to the leuco xanthene acid,

which is then oxidized to the dye with sodium dichromate [417].

132

Sulforhodamine G (C.I. Acid Red 50) is obtained similarly from 3-ethylamino-4-methylphenol. For both dyes, iron(III) chloride can be used in the oxidation instead of sodium dichromate. The sulforhodamines are brilliant red, fluoresce, and can be used as laser dyes [418].

The reaction of 2-sulfobenzoic acid anhydride with resorcinol in the presence of phosphorus oxychloride gives the *3,6-dichloro-9-* (*2-sulfophenyl*)*xanthylium betaine* (**133**).

133

Both chlorine atoms can be replaced by substituted anilines. This reaction gives monosulfonic acids of the diaminoxanthene series, which, as sparingly soluble betaines, have pigment character and can be used to produce printing inks [419]. Sulfonation yields soluble dyes that give brilliant red and violet shades on wool [44].

Violamines are produced by nucleophilic substitution of chlorine. Dichlorofluoran lactone, which is used as an intermediate, is formed from fluorescein (see Section 10.2.3) and phosphorus oxychloride. After replacing both chlorine atoms with an aromatic amine and introducing a sulfonic acid group, violet dyes with high brilliance are obtained. With *o*-toluidine *Fast Acid Violet ARR* (**134**) (C.I. Acid Violet 9, C.I. 45190, *trade name* Sandolan Violet E-R, Sandoz) is obtained.

134

10.2.3. Hydroxyxanthene Dyes

Reaction of phthalic anhydride with aromatic polyhydroxy compounds gives hydroxyxanthene dyes.

Fluorescein. The most well known hydroxyanthene is fluorescein [*518-47-8*] (**135**) (C.I. Acid Yellow 73, C.I. Solvent Yellow 94, C.I. 45350, *trade name* Basacid Yellow 226, BASF). It is produced industrially by melting resorcinol and phthalic anhydride at 200 °C [420].

135

Production Example. Phthalic anhydride (35 kg) is added gradually to 50 kg molten resorcinol. The reaction mixture is heated to 200 – 205 °C and the melt is kept at this temperature for 30 h. After cooling, the crude melt is ground up and stirred with dilute sodium hydroxide solution. Undissolved material is removed by filtration, and fluorescein is precipitated with hydrochloric acid. Yield: 72 kg.

Uses. Fluorescein is not important in textile dyeing. Its alkali salt is used to dye liquid bath preparations. Ca. 250 t of fluorescein are produced annually. Esters of fluorescein are used for the quantitative fluorimetric determination of the activity of ester-cleaving enzymes since the fluorescence increases as cleavage of the ester bond progresses [421]. The thyroxine conjugate of 6-carboxyfluorescein (bonding to thyroxine via the carboxyl group) can be used in biochemical analysis to determine quantitatively the thyroxine content in blood. In an immunoassay the conjugate is bonded to an antibody in competition with the thyroxine to be determined. The intensity of the polarized fluorescent light emit-

ted by the conjugate is therefore inversely proportional to the quantity of free thyroxine [422].

Eosin Dyes. The reaction of fluorescein with bromine gives eosin dyes. *Eosin G* [*17372-87-1*] (**136**) (C.I. Acid Red 87, C.I. Solvent Red 43, C.I. Pigment Red 90, C.I. 45380) was produced by H. Caro and A. von Baeyer in 1874 by bromination of fluorescein in alcoholic solution [423].

136

Eosin G is *used* to dye cosmetics [424]. The aluminum salt and the lead salt of eosin G are pigments that are used as printing inks for books and newspapers, mainly in the United States. The consumption is ca. 200 t/a.

Erythrosin B [*16423-68-0*] (C.I. Acid Red 51, C.I. Food Red 14, C.I. Pigment Red 172, C.I. Solvent Red 140, C.I. 45430) is a tetraiodo derivative of fluorescein and is obtained by treating fluorescein with iodine and iodic acid in alcohol. The dye is isolated as the disodium salt. It is used in the food and cosmetic industries. The market volume is ca. 600 t/a.

Hydroxyxanthene dyes can also be produced from di- and tetrachlorophthalic acid. Bromination gives the *phloxin* and iodination the *rose bengal dyes*.

Rose bengal GTO [*18265-55-9*] (**137**) (C.I. Acid Red 93, C.I. Solvent Red 47, C.I. 45435) is the tetraiodinated derivative of the dye produced from dichlorophthalic acid [425].

137

Rose bengal, erythrosin, and eosin are photosensitizers that are used, e.g., as catalysts for curing epoxy and poly(methyl methacrylate) resins [426]. They also have phototoxic properties and act as insecticides toward adult insects and larvae [427].

Gallein (**138**) (C.I. Mordant Violet 25, C.I. 45445) is produced by condensation of 2 mol equivalents of pyrogallol with 1 mol equivalent of phthalic anhydride [428].

138

Gallic acid can be used instead of pyrogallol. The dye colors chrome mordanted wool pure violet.

11. Thioxanthene Dyes

Treatment of bis(4-dimethylaminophenyl)-methane with the reaction product of sulfur and oleum gives the violet thioxanthene dye thiopyronin [*2412-14-8*] (**139**) [429].

139

Thioxanthene dyes can be used in photography [430] and are of interest as sensitizers in photodynamic therapy [431].

3,6-Bis(dimethylamino) thioxanthone (**140**) can be used as starting material for the production of benzopyranothioxanthene dioxides, such as **141**, which can be used as color formers [432].

140

141

Similar to the xanthene series, thioxanthene lactones are obtained from phthalic anhydride and substituted 3-aminophenylthiols. The thioxanthene lactones can be used as color formers [433].

12. Other Ring-Closed Triarylmethane Dyes

12.1. Cationic Dyes

Fluorene Derivatives. If the two carbon atoms *ortho* to the central carbon in triphenylmethane dyes are bonded directly, fluorenes are obtained. Ring closure gives a significant shift of the absorption maximum toward longer wavelengths (see Section 1.2).

The dye **142** formally derived from crystal violet was produced initially from 3,6-bis(dimethylamino)fluorenone and lithium 4-dimethylaminophenylide [434].

142

In an industrially more suitable synthesis, crystal violet is treated with sulfuric acid in the presence of catalytic quantities of phosphate at >150 °C. A sulfonic acid group is initially introduced *ortho* to the central carbon atom. Rearrangement and hydrolysis under oxidizing conditions lead to the fluorene dye (**142**) [435], which colors polyacrylonitrile fibers blue with a green cast [436].

Dyes with an Isopropyl Bridge. Triphenylmethane dyes that are bridged by an isopropyl group are obtained by condensation of Michler's hydrol with 3-dimethylaminopropenylbenzene and subsequent oxidation of the leuco compound. Dye **143** can be used in photography [437].

143

Dye **144** is obtained similarly by ring closure of 4,4′-bis(dimethylamino)-2-propenyldiphenylmethane.

144

As with Michler's hydrol, the absorption maximum of this dye is 607 nm. Because of restricted rotation, however, it exhibits intense red fluorescence. It emits at 640 nm and is used as the active medium in dye lasers both in solution [438] and in polymer resins [439].

12.2. Nonionic Derivatives (Triphenylmethanol Derivatives and Lactones)

Fluorene Lactones. Because they absorb in the near IR, fluorenes have attracted interest as color formers. After synthesis of a derivative of crystal violet lactone with an amino group *ortho* to the central carbon atom (**145**), the amino group is diazotized and the diazonium salt is cyclized to the fluorene (**146**) in the presence of copper powder [440].

145

146

Fluorene lactones with a pyridine or pyrazine ring in the 9-position [440] and derivatives with alkenylamino and substituted alkylamino groups [441] have also been produced by this method. Higher-purity products with improved yields can be obtained if the cyclization is carried out in phosphoric instead of sulfuric acid [442].

An alternative process involves the cyclization of phthalides with aluminum trichloride. Under nonoxidizing conditions, a leuco fluorene dye can be produced from crystal violet [443]. If the melt reaction of triaminotriphenylmethane lactones, such as crystal violet lactone, is carried out in the presence of urea and air, oxidation to the fluorene lactone occurs in addition to cyclization. Addition of aluminum trichloride hexahydrate suppresses dealkylation and yields purer products [444].

Cyclization of 3-(4′-dimethylaminophenyl)-3-(4′-dimethylaminonaphthyl)-6-dimethylamino-phthalide does not give a fluorene. Instead, cyclization occurs with the 5-position of the 1-naphthylamine group. A spirobenzanthracenephthalide (**147**) is obtained [445].

147

Dihydroanthracenes. By oxidation with atmospheric oxygen, the colorless dihydroanthracenes (**148**) are converted to dyes. They are produced by condensing Michler's hydrol with 3-dimethylaminobenzyl alcohol and cyclizing the leuco tris(dimethylaminophenyl)methane dye, which has a hydroxymethyl group *ortho* to the central carbon atom, in the presence of acid [446].

148

13. Toxicology

Toxicological data of important triarylmethane and diarylmethane dyes are summarized in the following:

Michler's ketone has been found to induce hepatocellular carcinomas and hemangiosarcomas in rats and mice [447].

Auramine. Many authors found that auramine showed no mutagenic effects in the Ames test [448–450]. A weak mutagenic activity was observed only in strains TA 98 and TA 1537 with metabolic activation. This activity is suggested to be attributed to a contaminant.

Technical-grade auramine O has been found to induce hepatomas in rats and mice on oral administration [451], [452].

In a test conducted by Kirsch and coworkers [453], auramine, however, showed no activity when fed to rats for two years at lower dose levels of 50, 100, and 200 mg/kg in the diet. The inactivity at lower doses suggests that impurities in the commercial dye preparation may be responsible for the activity observed in tests at the higher 1000-mg/kg dose [451], [452].

Other studies [454] also strongly suggest that contaminants in commercial auramine dye preparations may be responsible for mutagenic activity. A commercial preparation was found to induce DNA damage. The preparation contained as a major contaminant Michler's ketone, which is known to have carcinogenic activity. More importantly, tests on the same systems after purification of the dye sample by TLC were negative.

Case and Pearson established [455] an increased occurrence of bladder cancer among workers involved in the production of auramine O and fuchsin in the United Kingdom between 1910 and 1952. However, in a detailed study in which persons involved in auramine production in the BASF plant at Ludwigshafen participated, the trends or observations concerning auramine discussed by Case and Pearson could not be confirmed [453], [456]. According to this study there is no evidence that auramine should be regarded as carcinogenic.

Malachite green exhibits acute oral toxicity. Inhibition of algal growth, acute lethal toxicity

in fish, and inhibition of activated sludge have also been observed [457].

Pararosaniline induces tumors in rats and mice. It can definitely be classed as having mutagenic potential [457].

Methyl violet inhibits the growth of algae and is toxic to fish [457].

Crystal Violet. In animal experiments, crystal violet exhibits acute oral toxicity. The toxic effects occurring in humans, such as nosebleeds, contact sensitization, nausea, gastrointestinal irritation, and mucosal ulceration, refer to case reports and are not the results of systematic clinical tests. Crystal violet is toxic to activated sludge [457]. Long-term feeding experiments with rats and mice have led to increased occurrence of tumors in various organs [458].

Acridine Dyes. Toxicological investigations indicate that aminoacridines such as acridine orange 2 G (**104**) have mutagenic potential. Light either enhances the effect or is necessary for the activity observed [457].

Rhodamine B has been shown to cause point mutations in the Ames test and chromosome aberrations in a number of in vitro systems. Long-term feeding studies [459] in rats and mice have produced positive oncogenic responses, while short-term carcinogenicity assays [451], [459–462] have been predominantly negative. The possibility has been raised that contaminants contribute to the tumorigenicity.

1. Introduction

Tungsten (wolfram, W), atomic number 74, relative atomic mass 183.85, is a transition metal in the third long period and group 6 of the periodic table. Its electron configuration is [Xe] $6s^2 4f^{14} 5d^4$ but can also be interpreted as [Xe]$6s^1 4f^{14} 5d^5$. The naturally occurring isotopes (abundances in parentheses) have relative atomic mass 180 (0.14 %), 182 (26.42 %), 183 (14.40 %), 184 (30.64 %), and 186 (28.41 %). There are also 17 known artificial isotopes and isomers from ^{137}W to ^{189}W, with half-lifes between 14 μs and 140 d In nature, tungsten occurs only in a chemically combined state (mainly as tungstate). The metal, which has a silvery white luster, has a very high density (19.3 g/cm^3 at 20 °C), and the highest melting point (3410 °C) of all the metallic elements.

History. Long before elemental tungsten was discovered (1783), the mineral wolframite was known, e.g., in the tin mines of Saxony and Bohemia. It was first described in 1574 by Lazarus Ercker, and thought to be a tin mineral that contained arsenic and iron.

The name wolfram is derived from the word wolf, i.e., the wolf that devoured tin. A foam (Latin: *lupi spuma*, wolf's foam) was formed on the molten tin during the smelting of tin ore, reducing the yield of tin.

In 1757, a new mineral with density 6 (scheelite) was described by A. F. Cronstedt. He named this "tungsten" (Swedish: *tung sten*, heavy stone) and considered it to be a calcium-containing iron mineral. In 1781, C. W. Scheele analyzed the ore and announced that it contained calcium with a hitherto unknown acid. He described digesting the mineral with K_2CO_3, precipitating the unknown acid with nitric acid, decomposing the mineral with mineral acids, and dissolving the precipitated acid in ammonia. In the same year, T. Bergmann suggested that the metal might be obtained by reduction of the acid with carbon.

In 1783, the element was produced by the brothers J. J. and F. de Elhuyar from wolframite by reduction of the oxide with carbon. They named it wolfram. In 1786, the hardening of steel was described by H. I. du Monceau. In 1821, K. C. von Leonhard proposed the name scheelite for the mineral $CaWO_4$.

The real chemistry of tungsten originated with R. Oxland (1874), who patented a method for producing sodium tungstate, tungsten oxide, and metallic tungsten. He was also the first to propose a method for the production of ferrotungsten. The possibility of using tungsten as an alloying element to increase the hardness of steel could not initially be realized because of the high price of the metal.

The developments that led to the industrial use of tungsten began in 1890 with the production of WC by H. Moissan. They may be summarized as follows:

In 1900, the Bethlehem Steel Company announced the first high-speed, high-temperature steel at the Paris Exhibition.

In 1903, the first tungsten filaments for incandescent lamps were produced in Hungary by the method patented by Just and Hanamann.

In his patent of 1909, W. D. Coolidge described the production of ductile tungsten wire by powder metallurgy, a process that has not changed in its essential features even today. This process represents the first industrial use of powder metallurgy.

In 1922, the Osram Research Association obtained a patent for the production of tungsten carbide – cobalt hard metals.

Four years later, the Krupp organization introduced the first hard metal cutting tool at the Leipzig Exhibition.

The increasing use of hard metals in the machining of steel and in the mining industry (energy production) led to a great increase in the demand for tungsten. As a result of the uncertain availability of raw materials in crisis situations and the increased use of tungsten materials in the armaments industry (hard metals, tungsten-containing heavy metals), the metal has become of strategic importance.

All later materials developments are essentially only a broadening and diversification of the early work on the production of the metal and

its alloys. Tungsten compounds are becoming increasingly important, e.g., as the active components in catalysts.

Continuously increasing demand up to the 1980s led to the constant exploration of tungsten deposits and the opening of mines and processing plants. However, owing to a fall in price and demand, a large number of mines have been closed since 1985, especially in the industrialized countries.

In terms of quantity, tungsten is the second most important high-melting metal, after molybdenum; however, it is the most important refractory metal used in powder metallurgy.

General information on tungsten and its alloys and compounds can be found in [1–7]. A summary of the early history can be found in [8].

2. Properties

2.1. Physical Properties

Tungsten has the highest melting point of all metals, exceeded only by elemental carbon and the metallic monocarbides of niobium, zirconium, tantalum, and hafnium. The extremely high bonding energy (due to the half-filled 5*d* shell) leads to extreme values of other properties. For example, tungsten has the lowest vapor pressure of all metals, the lowest compressibility, an extremely high density, a high modulus of elasticity, low thermal expansion, and high thermal conductivity.

Some physical properties of tungsten follow [1], [3], [9]. (see left column)

Mechanical and Metallurgical Properties. Pure metallic tungsten has a body-centered cu-

bic structure, is brittle at room temperature, and is therefore not suitable for cold forming. At elevated temperatures (ca. 100 – 500 °C) it is transformed into the ductile state. The temperature of this sharply defined transformation is mainly dependent on the purity and the history of deformation and heat treatment of the material. The transformation temperature is increased by the presence of extremely small amounts of interstitially soluble elements, e.g., oxygen, carbon, and nitrogen, which lead to intergranular precipitation. The transformation temperature decreases with increasing deformation; highly deformed products such as thin sheet and wire are ductile at room temperature. This is mainly due to the distribution of the precipitated impurities over a larger intergranular area, and the formation of a fine-grained fibrous structure which tends to prevent intergranular failure perpendicular to the fiber direction. In the fiber direction, the tendency toward intergranular failure is more or less constant.

Addition of rhenium can cause the transformation temperature to fall below room temperature, even for only slightly deformed products (see Section 5.1). With extremely pure single crystals, brittle – ductile transformation temperatures as low as −190 °C are observed.

The grain size and grain structure have a great influence on the mechanical properties of tungsten. These can be controlled by sintering conditions, type of deformation, degree of deformation, and annealing processes during and after machining (intermediate annealing, stress-relieving annealing, soft annealing, recrystallization annealing, see Sections 4.6, 4.7).

Consequences of the high bonding energy of tungsten include its high ultimate strength and yield strength, high modulus of elasticity, and high recrystallization temperature.

The hot strength of tungsten, like its elongation, depends on its deformation and annealed condition, and can vary widely at a given temperature (Fig. 1). The hot strength of tungsten is exceeded only by that of rhenium. The upper limit for the hot tensile strength corresponds to a stress-relieved sheet, and the lower limit to a recrystallized sheet. At ca. 1500 °C, both limiting curves coincide, i.e., at this temperature the tungsten completely recrystallizes as it is heated to the tensile testing temperature (and therefore at temperatures above this) independently of the starting condition of the tungsten, so that is always has the hot strength of recrystallized tungsten. The results of hot tensile testing are to some extent influenced by the strain rate.

Figure 1. Hot tensile strength of tungsten sheet, thickness 1 mm, strain rate 15 % min^{-1} [3]

The relation between temperature and fracture strain of recrystallized tungsten sheets is shown in Figure 2.

Figure 2. Effect of temperature on fracture strain of recrystallized tungsten sheet [3]

No allotropic transformations of group 6 metals are known which could lead to changes in their properties. The solubility of the nonmetals carbon, silicon, oxygen, nitrogen, and water in these metals is very small. Therefore, impurities in the form of interstitially dissolved nonmetals have a smaller effect on the mechanical properties than is the case with other transition metals, but have a very significant effect if the solubility limits are exceeded. Carbides, silicides, nitrides, and oxides are then formed [9], and the inclusions have a marked effect on grain shape and size.

As the solubility of interstitial impurities (O, N, C) at room temperature is well below 0.1 µg/g, and the solubilities, even at the eutectic temperature, are only 0.01 – 0.1 % [10], the insoluble excess segregates at the grain boundaries on cooling. Oxide impurities, in particular, considerably reduce intergranular strength. With carbide impurities, a beneficial effect on ductility is apparent, depending on the form of the carbides. The effect of nitrides is not yet fully understood. In deformed tungsten, it leads to

marked anisotropy of the mechanical properties in the direction of deformation, so that sheet and bar tend to split. In recrystallized tungsten, the intergranular impurities enable plastic deformation to take place above the transformation temperature, as already mentioned [9].

2.2. Chemical Properties

Tungsten is stable in air up to 350 °C, but begins to oxidize above 400 °C. A thin film of blue tungsten oxides forms on the surface, and this at first prevents further attack. As the temperature increases, cracks develop in the oxide film, and these favor oxidative attack. Above 800 °C, rapid oxidation takes place with formation of WO_3, which sublimes. In oxygen, tungsten burns at 500 – 600 °C. Tungsten is stable to mineral acids in the cold, and is only slightly attacked at higher temperatures. Its stability to cold and hot hydrofluoric acid is of practical importance. Mixtures of hydrofluoric and nitric acids dissolve tungsten very readily, the tungsten remaining in solution because of the complexing effect of the fluoride ions. Hydrogen peroxide is a good solvent for finely divided tungsten; the peroxo complexes so formed keep the tungsten in solution. Alkaline solutions do not attack tungsten, which is also very stable to molten alkalis. In the presence of oxidizing agents (Na_2O_2, $NaNO_2$, or $NaNO_3$), rapid dissolution takes place.

Tungsten is stable to molten glass and silica up to 1400 °C. At higher temperatures, it reacts with many elements, e.g., B, C, Si, P, As, S, Se, Te, and the halogens. It reacts with fluorine at lower temperatures. It is stable to chlorine up to 250 °C, and to bromine and iodine up to 500 °C. It is very stable to gaseous nitrogen and ammonia up to 1400 °C. There is no reaction with hydrogen. With carbon monoxide, the hexacarbonyl is formed at low temperatures, and the carbide above 800 °C.

3. Raw Materials

3.1. Natural Resources

The average concentration of tungsten in the earth's crust is 1.5 g/t. It is thus a rare element.

Minerals. Tungsten occurs only in combined form. The most important tungsten minerals are [4]:

Anthoinite	$Al(WO_4)(OH) \cdot H_2O$
Cuprotungstite	$Cu_2(WO_4)(OH)_2$
Ferritungstite	$Ca_2Fe_2^{2+}Fe_2^{3+}(WO_4)_7 \cdot 9\,H_2O$
Raspite	$PbWO_4$
Russellite	Bi_2WO_6
Sanmartinite	$ZnWO_4$
Scheelite	$CaWO_4$
Stolzite	$PbWO_4$
Tungstenite	WS_2
Tungstite	$WO_3 \cdot H_2O$
Ferberite	$FeWO_4$ with up to 20 % $MnWO_4$
Hübnerite	$MnWO_4$ with up to 20 % $FeWO_4$
Wolframite	$(Fe, Mn)WO_4$

With the exception of tungstenite, all the minerals are tungstates, but only scheelite and the wolframite group are of industrial importance. The most important properties of scheelite and the wolframites are listed in Table 1 [4].

Scheelite is often associated with the isomorphous calcium molybdate (powellite). Pure scheelite has a blue fluorescence in ultraviolet light, becoming white with a molybdenum content of ca. 1 %, and yellow above this concentration. This property is utilized in prospecting for scheelite.

Wolframite is a general term for a mixed crystal series (with no miscibility gap) of Fe(II) and Mn(II) tungstates. The minerals between pure iron tungstate and 20 % $MnWO_4$ are known as ferberite. Manganese tungstate and mixed crystals containing up to 20 % $FeWO_4$ are known as hübnerite.

The minerals tungstite and cuprotungstite have achieved a small degree of industrial importance.

Deposits. All tungsten deposits are of magmatic – hydrothermal origin. During cooling of the magma, differential crystallization occurs, first of basic and later of slightly acidic rocks, and enrichment of tungstate and other ions takes place, accompanied by an increase in the concentration of silica in the remaining magma and the hydrothermal solution. Tungsten cannot replace the main elements such as Fe, Mg, Ca, Al, and Si in the basic and slightly acidic rocks, and is not incorporated in the first material to crystallize. Therefore, scheelite and

Table 1. Physical and chemical properties of wolframites and scheelite

wolframite are often to be found in the last crystallization stage of a magma, i.e., the pegmatites and the material crystallized from hydrothermal solutions.

There are many types of deposit:

1) Pegmatite deposits are relatively rare and can contain wolframite and scheelite. The tungsten minerals are crystallized together with the pegmatitic minerals.
2) Greisen deposits contain wolframite, and are formed by the mineralization of intrusive rock (and of the rock it penetrates) by hydrothermal solution processes.
3) Contact-metasomatic deposits are the commonest type and are of pure scheelite. They are formed by the reaction between limestone and residual magma or hydrothermal solutions that penetrate into it.
4) Vein deposits can contain wolframite and scheelite. Hot magma causes cracks and faults in the surrounding rock, into which hydrothermal solution is injected. It then crystallizes.
5) Pneumatolytic deposits are rare, and are formed by the transport of volatile tungsten compounds in the gas phase.
6) Secondary enriched deposits are very rare and contain tungstite formed by weathering of wolframite.
7) Placer deposits, in which high density materials become concentrated in river sediments, are also very rare.

The gangue minerals differ not only among the various deposits, but can also vary greatly within a single mine. This is easily understood, as the various types of deposits can often occur together in one mine. The commonest types of gangue minerals are: quartzite, various silicates, limestone, magnesite, fluorspar, apatite, and various sulfide ores.

The concentration of workable ores is 0.1 – 2.5 % WO_3, contents of ca. 2 % being rare. The average content is ca. 0.5 % WO_3. The lower limit of workability depends on the ore type, gangue composition, and world market price. It fluctuates between 0.1 and 0.3 % WO_3.

Reserves. Tungsten deposits occur throughout the younger mountain ranges, e.g., the Alps, the Himalayas, and the circum-Pacific belt. World tungsten reserves (in 10^3 t) in 1985 are listed here [11]. (see below)

These figures include reserves that are known, but have so far not been found to be economically workable. This type of information is partly based on estimates, as countries such as the People's Republic of China and the former Soviet countries have not published any accurate information. By far the largest reserves are in China (35 %, but may exceed 50 %), followed by Canada (19 %), and the former Soviet Union (14 %). At the current world annual consumption rate of 30 000 t, these known reserves of ore are likely to last for ca. 120 years. Of the ore deposits, 75 % are of scheelite and 25 % wolframite, with a few in which both minerals occur together [12]. Over half the reserves of ore are in developing countries.

3.2. Tungsten Scrap

Tungsten scrap has been used as a raw material for production of pure tungsten for more than 50 years. There are several reasons for this:

The low concentration in the earth's crust results in a consistently high cost of the metal; recycling has always been economic.

The concentration of tungsten in the various types of scrap is always considerably higher (30 – 99 %) than in any ore, so there are no concentration costs.

The accompanying elements in scrap do not cause serious problems during chemical processing.

High demand and consequent high prices from 1975 to 1985 led to an increase in scrap processing, and made lower-grade scrap (grinding wheel swarf and dusts) more attractive for reuse [13]. Since then, the amount of scrap used as a percentage of the total tungsten raw materials has increased still further in spite of falling price and demand. This is largely because environmental regulations have become increasingly strict, making it impossible to dispose of scrap with even a low tungsten content, e.g., wheel swarf or similar materials. Consequently, scrap is classified as a primary tungsten raw material. This is shown in Figure 3, which also shows that approximately one-third of demand is supplied from scrap [14].

Figure 3. Tungsten flowchart

The processing of scrap is environmentally beneficial. No energy is required for mining and preparation, and no chemicals for concentration processes. This reduces both atmospheric pollution and chemical waste. Especially important for the future is the fact that scrap recycling conserves reserves of ore.

Scrap is classified as either "hard" or "soft". Soft scrap is finely divided material, e.g., powder, dust, grindings, and turnings, with tungsten content 10 – 98 %. Hard scrap is in lump form (sintered material, scrap bar and sheet, wire, etc.) with tungsten content 40 – 99.9 %.

4. Production

4.1. Ore Beneficiation

Most tungsten ores contain less than 1.5 % WO_3. Therefore, ore-dressing plants are always in close proximity to the mine to keep transport costs low. The first steps in the procedure are crushing and milling to liberate the tungsten mineral crystals from the gangue materials. The final grain size to which the ore must be reduced depends on the size of mineralization present in the tungsten ore body. This can be quite different from deposit to deposit. The finer the mineralization, the more costly the pretreatment and the lower the recovey. No more crushing and milling should be applied than is absolutely required, to minimize losses.

Scheelite Ore. After crushing, coarsely crystallized scheelite can be concentrated by gravimetric methods (hydrocyclones, tables, spirals, etc.). Finely mineralized scheelite, however, has to undergo froth flotation. A very high purity may be obtained by gravity methods (sometimes >90 % scheelite in the concentrate). The yield is normally 60 – 70 % and sometimes 80 – 90 %. The flotation process allows recoveries of 80 – 90 %. Modern plants combine gravimetric and flotation methods because on disintegration some of the scheelite crystals are broken into fine particles which are lost if only gravity methods are used (scheelite is very brittle). The fine particles can be recovered in a subsequent flotation step. Typical commercial concentrates contain >70 % WO_3. Fully downstream integrated plants that process their concentrates themselves keep the final WO_3 concentration in the flotation process low (5 – 40 %) to minimize losses, giving overall yields of >90 %.

Wolframite Ore. Gravity methods are used for wolframite ore, sometimes in combination with magnetic separation. The weakly magnetic wolframite properties enable a further concentration. Commercial concentrates should assay >65 %.

4.2. Pretreatment of Ore Concentrates and Scrap

Hydrochloric acid leaching of scheelite concentrates at room temperature is used to reduce phosphorus, arsenic, and sulfur content [4].

Calcination in air (500 – 600 °C) is used to oxidize organic flotation agents which could have a detrimental effect on subsequent processing [15], [16]. Also, in mixtures of concentrates with high sulfide and calcium carbonate contents, gypsum is formed [16], and arsenic and sulfur are removed if they are present in high concentrations in wolframites.

Grinding is necessary for scheelite concentrates produced by gravity methods, and with all wolframite concentrates.

Oxidation of soft scrap by heating in air at 700 – 800 °C allows the tungsten to be dissolved in subsequent pressure leaching processes [17].

4.3. Hydrometallurgy

This section deals with the production of high-purity ammonium paratungstate (APT), which is now the most important raw material for all other tungsten products. Only the modern process is described; a comparison with classical methods [7] is given in Figure 4. The most important differences are:

1) The use of solvent extraction instead of precipitation of $CaWO_4$ to convert the sodium tungstate solution to ammonium tungstate solution, followed by decomposition to H_2WO_4.
2) Conversion of the tungsten in aqueous solution to a solid compound by crystallization rather than precipitation. Each crystallization is a slower process than immediate precipitation, and therefore leads to a purer product.

The advantages of the modern process are:

1) The possibility of using various raw materials (wolframite, scheelite, scrap)
2) Better energy efficiency
3) Less labor required
4) Ease of automation
5) Higher yields
6) Uniformity and higher purity of the product

A flow diagram of a modern APT production plant based on various raw materials is shown in Figure 5.

4.3.1. Digestion

Wolframite concentrates can be dissolved either at atmospheric pressure with concentrated NaOH solution (40 – 50 %, 15 mol/L) at 100 – 145 °C followed by dilution [18], or by high-pressure digestion with dilute NaOH solution [19].

$$(Fe, Mn)WO_4 + 2\,NaOH \rightarrow Na_2WO_4 + (Fe, Mn)(OH)_2$$

Scheelite concentrates are always leached with Na_2CO_3 solution under pressure [4]. The process requires a large excess of reagent, but gives a milder reaction with respect to dissolution of gangue, and can be carried out in mild steel autoclaves (NaOH treatment requires Inconel cladding).

Figure 4. Comparison of classical and modern WO_3 production

Figure 5. The modern APT process

Figure 6. Tungsten solvent extraction

$$CaWO_4 + Na_2CO_3 \rightarrow Na_2WO_4 + CaCO_3$$

Mixtures of concentrates of wolframite and scheelite can be dissolved by Na_2CO_3 solutions with addition of NaOH under pressure [20]. Oxidized soft scrap is digested with NaOH solution, as in the treatment of wolframite [15].

Information on the parameters and yields for various chemical leaching processes is given in Table 2.

4.3.2. Purification

The sodium tungstate solution obtained by leaching the ore contains amounts of dissolved impurity elements depending on the composition of the raw material. If the concentration of these elements is too high, subsequent processing may be disturbed or the end product may have too high an impurity level. Purification is carried out by precipitation and filtration.

Silicate Precipitation. Silicates are common gangue minerals which dissolve on pressure leaching, at least partially. Dissolved silicate can be precipitated by the addition of an aluminum sulfate or magnesium sulfate solution, or a mixture of the two at pH 8 – 11 [21]. The chemistry of the precipitation is complex and has not been investigated in detail. With higher silicate content, a two-stage precipitation with a mixture of aluminum and magnesium sulfates is preferable, enabling the SiO_2 content to be reduced to 30 –60 mg/L [4].

This precipitation technique reduces not only the silicate content, but also the phosphate and fluoride concentration. Precipitation is first performed with magnesium sulfate at pH 10 – 11, and then with aluminum sulfate at pH 7 – 8 [22].

Molybdenum Precipitation. Molybdenum is a very common companion element in tungsten ores. It remains in the concentrate and goes into solution on chemical digestion, either completely or partially. Precipitation is carried out by adding excess sodium sulfide to the neutral or mildly alkaline solution, forming thiomolybdate:

$$MoO_4^{2-} + 4\,S^{2-} + 4\,H_2O \rightarrow MoS_4^{2-} + 8\,OH^-$$

Table 2. Typical parameters for pressure leaching of tungsten raw materials

	Scheelite concentrate	Woframite concentrate	Oxidized scrap
Particle size, µm	<44 to <90	<44	<100
Temperature, °C	190 – 225	175 – 190	150 – 200
Pressure, MPa	1.2 – 2.6	0.8 – 1.2	0.5 – 1.2
Time, h	1.5 – 4	4	2 – 4
Reagent concentration, %	10 – 18 (Na_2CO_3)	7 – 10 (NaOH)	20 (NaOH)
Molar ratio, WO_3 : reagent	1 : 2.5 – 4.5	1 : 1.05	1 : 1.4

The solution is then acidified with sulfuric acid to pH 2.5 – 3.0. This causes the molybdenum to be precipitated as the trisulfide [20]:

$$MoS_4^{2-} + 2\ H_3O^+ \rightarrow MoS_3 + H_2O + H_2S$$

This purification stage is not only effective for Mo, but also removes a number of other elements that form insoluble sulfides, e.g., As, Sb, Bi, Pb, and Co.

4.3.3. Conversion of Sodium Tungstate Solution to Ammonium Tungstate Solution

In modern plants, this reaction is now carried out exclusively by solvent extraction or ion exchange resins. The sodium ion concentration must be reduced from ca. 70 g/L to <10 mg/L, as sodium levels >10 ppm in the APT cause problems during the reduction to metal powder.

4.3.3.1. Solvent Extraction [4], [23], (Fig. 6)

The sodium tungstate solution (pH 2 – 3) is contacted with the organic phase, which extracts the isopolytungstate ions as an ion associate complex. Mixtures of tertiary or secondary aliphatic amines (e.g., trioctylamine) with isodecanol and kerosene form the organic phase. The amine is the reagent that forms the ion associate complex, the isodecanol increases the solubility of the complex (modifier), and kerosene is the solvent.

$$5\,R_3NH^+ + [HW_6O_{21}]^{5-} \rightarrow (R_3NH)_5HW_6O_{21}$$

The extract is washed with deionized water, and the isopolytungstate is then reextracted with dilute ammonia solution into an aqueous phase:

$$(R_3NH)_5HW_6O_{21} + 5\,OH^- \rightarrow [HW_6O_{21}]^{5-} + 5\,(R_3NH)OH$$

The solvent goes through a regeneration stage and is then returned to the extraction process.

4.3.3.2. Ion Exchange Process [24], [25]

This process is now used only in small plants in the People's Republic of China. A strongly alkaline ion exchange resin in the chloride form is used. On contact with the sodium tungstate solution, the tungstate is adsorbed. Desorption is carried out with ammonium chloride solution. Elements that form heteropolytungstates, e.g., Si, P, As, and Mo, can be removed.

4.3.4. Crystallization of Ammonium Paratungstate (APT) [26]

This compound has the formula $(NH_4)_{10}(H_2W_{12}O_{42}) \cdot 4\,H_2O$.

On evaporation of the isopolytungstate solution, water and ammonia are distilled, the pH of the solution decreases, and the sparingly soluble APT crystallizes [27], [28]. The ammonia – water mixture is condensed and recycled to the solvent extraction process. The crystallization conditions are used to control the physical properties that influence the subsequent processing to give tungsten powder. The process is carried out batchwise or continuously in recirculating crystallizers with partial recycling of mother liquor (to maintain the concentration of impurities in the mother liquor and hence in the crystals formed). Owing to the low solubility of APT compared with the impurities in the mother liquor, this process step represents not only a conversion from the dissolved form to a solid, but also a very important purification (Table 3).

Table 3. Maximum impurity concentrations in APT crystallization

Element	Feed solution, mg/L	Mother liquor, mg/L	APT, ppm
Al	<10	<100 ∗ <3000 ∗∗	<10
As	<50	<2000	<20
F	<250	<3000	<10
Fe	<10	<200	<10
Mo	<10	<60	<20
Na	<10	<100	<10
P	<50	<400	<20
Si	<10	<200	<20
V	<100	<1200	<20

∗ In absence of fluoride.
∗∗ For fluoride concentration of ca. 4000 mg/L.

4.4. Calcination of APT [4], [21]

On heating APT to 400 – 800 °C, ammonia and water are evolved. This decomposition becomes more complete as the temperature and duration of heating are increased. The form of the solid phase is determined by the decomposition temperature, the retention time in the reactor, and the reduction potential of the decomposition atmosphere. If heating takes place with air addition, yellow WO_3 is obtained; with exclusion of air, blue oxide. In the blue oxide, some tungsten atoms are pentavalent, owing to H_2 reduction (NH_3 decomposition). Unlike the yellow oxide, blue oxide is not a single, well-defined chemical compound. It contains WO_3 together with the oxides $W_{20}O_{58}$ and $W_{18}O_{47}$, depending on the decomposition conditions, and also ammonium and hydrogen tungsten oxide bronzes (residual NH_3 and H_2O content). Nevertheless, it is currently used more than the yellow oxide.

On an industrial scale, calcination is usually carried out in rotary furnaces, more rarely in pusher furnaces. The former yield a more uniform product. The chemical composition and micromorphology of the oxide particles are determined by the duration and temperature of heating. The micromorphology is very important in the production of submicron tungsten powders.

4.5. Reduction by Hydrogen to Tungsten Metal Powder [29–31]

The production of tungsten metal powder is today carried out almost exclusively by the hydrogen reduction of high-purity tungsten oxides (WO_3, WO_{3-x}). Reduction of the oxide by carbon is now used only for the production of tungsten carbide (direct carburization). The reduction of tungsten halides (Axel Johnson process) has not become established on a large scale.

The reduction of tungsten trioxide or blue oxide can be controlled by the temperature and the water vapor partial pressure.

At lower temperatures (600 °C) and lower moisture contents, the reduction proceeds by solid-state diffusion of the oxygen out of the oxide, and can be represented by the following equation:

$$WO_3\,(s) + 3\,H_2\,(g) \rightarrow W\,(s) + 3\,H_2O\,(g)$$

On complete reduction, an oxide-pseudomorphic metal sponge is formed.

At higher temperatures and moisture contents, the reaction proceeds stepwise via the oxides $W_{20}O_{58}$, $W_{18}O_{47}$, and WO_2 to tungsten metal. Only the first transformation to $W_{20}O_{58}$ and each nucleation of a newly formed phase on further reduction are solid-state reactions. All other transformations are linked with gas-phase transport of tungsten as the volatile oxide hydrate $WO_2(OH)_2$, and are associated with a significant change in shape of the crystal faces. The formation of the vapor-phase oxide hydrate takes place by reaction of the corresponding suboxide with water formed in the reduction. The vapor pressure of the oxide – hydrate in equilibrium with a stable compound formed under the reaction conditions is lower than that in equilibrium with the continually decreasing amount of the unstable compound. As a result of these

gradients, chemical vapor transport (CVT) takes place, so that the higher oxide decreases in quantity, and the lower oxide increases. The interphase reaction can plausibly be divided into three steps:

1) Formation of $WO_2(OH)_2$ from the oxygen-rich compound with H_2O
   $WO_2\,(s) + 2\,H_2O\,(g)$
   $\rightarrow WO_2(OH)_2\,(g) + H_2\,(g)$
2) Transport of $WO_2(OH)_2$ to the compound of lower oxygen content
3) Reduction of $WO_2(OH)_2$ by hydrogen at the surface of the compound of lower oxygen content (or the metal)
   $WO_2(OH)_2\,(g) + H_2 \rightarrow W\,(s) + 4\,H_2O\,(g)$

Formation of a new phase must be preceded by nucleation. This takes place on the surface of the reacting oxide if the water vapor pressure is lower than the equilibrium water vapor pressure for the phase transformation concerned. The nucleus then continues to grow as described above.

Reduction on an industrial scale is carried out in pusher furnaces, in which the powder passes through the furnace in boats, or in rotary furnaces. Walking beam furnaces or furnaces with internal band conveyors are less often used. Furnaces are provided with several temperature zones controllable between 600 and 1100 °C. The flow of hydrogen is usually in a countercurrent direction, more rarely cocurrent, and a drying stage is always included in the circuit, as a large excess is used. The hydrogen acts not only as a reducing agent, but also carries away the water formed. The flow rate is therefore one of the parameters for controlling the water vapor partial pressure. Other control parameters are:

1) The amount of oxide charged to the furnace per unit time
2) The depth of the oxide bed
3) The porosity of the oxide bed (particle size and particle size distribution)
4) The moisture content of the hydrogen entering the furnace

The porosity and depth of the bed, in conjunction with the H_2 flow rate, determine the rate of diffusion of water vapor from the bed.

In practice, the average grain size of the tungsten powder (0.1 – 60 µm) is controlled empirically by setting the temperature, oxide quantity, heating time, and H_2 flow rate. In general, these have the following effects:

1) Fine Powder: lower temperature, low bed depth, long dwell time, and high H_2 flow rate. These conditions correspond to a low water vapor partial pressure (and hence a more rapid nucleation rate), low crystal growth rate via the gas phase, and short transport distances of $WO_2(OH)_2$. The furnace capacity is low.
2) Coarse Powder: high temperature, greater bed depth, lower heating time, lower H_2 flow rate. These conditions correspond to a high water vapor partial pressure, a lower rate of nucleation, and more rapid transport via the gas phase over longer distances. The furnace capacity is high.

In the powder bed, there is a water vapor concentration gradient, as diffusion from the interior takes longer than from the outer parts. This leads to a grain size distribution in the tungsten powder; the powder in the interior of the bed is coarser than that in the outer zones and at the surface.

Doping with low concentrations of alkali metals (Na or Li salts) catalyzes crystal growth during the reduction process, and enables coarser tungsten powders (100 – 200 µm) to be produced [32].

4.6. Production of Compact Metal

Conversion of tungsten metal powder to compact metal is carried out exclusively by powder metallurgy, i.e., by a heat treatment (sintering) of a compacted preform.

Compaction (→Powder Metallurgy and Sintered Materials, Chap. 5.). In the first step, the powder is compacted hydraulically or mechanically by a polydirectional pressure of 200 MPa (2000 bar) to produce preforms – rods or plates that have edge stability and are of the correct dimensions. Circular blanks with a low height/diameter ratio and small items such as pins are produced in automatic presses at high outputs. The raw material for this must consist of free-flowing granules similar to the granulated hard metals produced in spray drying equipment [33].

Sintering (→Powder Metallurgy and Sintered Materials, Chap. 6.). Pure tungsten is today sintered almost exclusively by the economic indirect sintering process. Furnaces for this consist of tungsten heating elements surrounded by radiation shielding made of tungsten sheets on the inside and molybdenum on the outside, and are purged with hydrogen as a protective gas. At maximum sintering temperature (2800 °C), sintering times of several hours are required. In the production of so-called non-sag tungsten for incandescent lamp manufacture, direct sintering, i.e., by passage of an electric current, is usual. In both processes, the sintered densities achieved are ca. 95 % of theoretical.

The weight of individual sintered tungsten components is usually 1 – 100 kg. The choice of optimum sintering parameters greatly influences the structure and hence the strength and ductility of sintered tungsten.

In the direct sintering process, very high sintering temperatures, and hence short sintering times can be used. However, the practical limits on rod dimensions and production rates are a considerable disadvantage, and electricity costs per kilogram are significantly higher than with indirect sintering. Also, the fixing points, which are poorly sintered, must be knocked off the rod, causing further loss. Disadvantages of the indirect sintering process include the high cost of the plant and heating elements. Nevertheless, overall this process is considerably more economic, and it is the only process that allows the sintering of preforms.

Another important aspect is that sintering is an extremely effective purification process, removing a high proportion of impurities from the material. The hydrogen flow rate during sintering should therefore be high enough to transport the impurities away.

Melting. Approximately since the 1950s, i.e., after the development of electric arc melting plants and high-capacity vacuum equipment, it has been possible to melt highly refractory metals on an industrial scale. Some time later, trials on plasma melting and electron beam melting of tungsten showed that these processes led to a product with extremely coarse crystals and hence poor working properties, so these melting processes are of no technical value for tungsten (unlike molybdenum and its alloys). Electron beam zone melting is in fact used in the production of single crystals of tungsten [5], but these products have only a few special uses as production costs are high.

4.7. Processing of Sintered Parts

4.7.1. Shaping

Completely dense, pore-free bodies cannot be obtained by sintering, the residual porosity being 3 – 10 %. To obtain a completely dense material, a complex multi-stage forming process is required. Tungsten can be shaped by all the usual forming processes, e.g., forging, rolling, extruding, and wire drawing. The first forming step is usually carried out at 1500 – 1700 °C. Many reheating stages are necessary in the first stages of shaping, as the heat is rapidly lost at these temperatures and a stress-relieving operation below the recrystallization temperature is often advantageous. Intermediate heating operations are necessary for recrystallization. The forming temperature is progressively reduced, since the recrystallization temperature decreases as forming proceeds. To give a well-defined fiber structure (high degree of deformation), a final cold forming can be carried out, as already stated.

Chipless Forming, Including Stamping and Cutting. The temperature range for the forming of tungsten has a lower limit, set by the transformation temperature, and an upper limit, set by the recrystallization temperature. Thin, strongly deformed sheet and foil have a pronounced structure in the longitudinal direction due to elongation of the grains during rolling. The bending properties along the direction of rolling are therefore different from those across it. Tungsten sheet should therefore always be bent perpendicular to the rolling or longitudinal direction. If bending in the longitudinal direction cannot be avoided, owing to the design, a much higher temperature is required.

Tungsten can also be formed at high temperatures by pressing, flow-turning (spinning), or forging.

Die stamping of tungsten sheet is possible if the working temperatures of the sheet and the tool are kept high.

Tungsten can be punched and forged at high temperatures. Blunt edges on punching tools and shears, or low punching or cutting temperatures can cause cracking and splitting.

Machining. Tungsten can be drilled, turned, milled, planed, and ground. However, machining operations require great experience and close adherence to optimum conditions [3]. Complex shapes and holes can be produced by spark erosion; the tungsten workpiece forms the anode and the working electrode the cathode. Suitable electrode materials can be based on tungsten – copper.

4.7.2. Mechanical Bonding of Tungsten to Tungsten and Other Metals

Rivets. Tungsten components can be bonded together or to components made of other metals by means of rivets, provided the joint need not be impermeable to liquids and/or gases. Tungsten rivets and round-head and countersunk molybdenum rivets can be used.

Brazing (→Soldering and Brazing). The parts to be joined must be free from grease, oils, oxides, or other impurities, and should preferably be etched immediately before brazing. As tungsten is very sensitive to oxidation, it is preferable to carry out the operation under a protective gas, hydrogen, or vacuum. Parts with a large surface area or of complex geometric shape should be brazed in a furnace with the aid of a special jig. If brazing temperatures exceed 1150 °C, there is a possibility of recrystallization. Typical brazing metals and temperatures are: Rh (1970 °C), Pd (1550 °C), CuNi 45 (1300 °C), etc. [3].

Welding (→Welding and Cutting). Tungsten has only moderate welding properties. The weld seams have a coarse-grained structure in the hot fusion zone, owing to recrystallization, and can therefore withstand only low mechanical stresses. If welding is unavoidable, weld seams should if possible be located in regions of low internal and mechanical stress. It is preferable to locate weld seams as far as possible from the edges or ends of fabricated articles.

Tungsten inert gas (TIG) welding can be performed in protective gas chambers. However, in electron beam welding, the melting and hot fusion zones are much more limited in size, so this technique is preferable for welding tungsten. It is advantageous to preheat the parts to be joined to ca. 700 – 800 °C by a defocused electron beam immediately before welding. Welded components should be cooled as slowlyas possible. Tungsten can be electron beam welded to tungsten – rhenium and molybdenum –rhenium alloys, copper, and stainless steel. Tungsten – rhenium alloys are recommended as filler metal for welding tungsten.

As fusion welding can be used only under certain circumstances, diffusion welding of tungsten to tungsten and to other metals is important. Despite the high melting point of tungsten, temperatures of 1300 – 2000 °C and pressures of 2 – 20 N/mm^2 give satisfactory joints. The diffusion welding of tungsten is carried out in either vacuum or pure hydrogen.

Thin intermediate layers in the form of films of nickel, platinum, rhodium, ruthenium, and especially palladium, considerably accelerate the diffusion processes.

Tungsten wires and small tungsten components can be bonded to fusible alloys based on iron – nickel – cobalt and to other metals by spot welding under a protective gas blanket. The use of small pieces of foil made of platinum, niobium, tantalum, or zirconium is recommended. Laser beam welding of tungsten is likely to become very important in the future.

4.8. Surface Treatment

Tungsten components can be degreased with trichloroethylene, perchloroethylene, and similar solvents.

Tungsten can be etched with alkaline and acid media. Whereas oxidized tungsten is more easily cleaned with alkaline etchants, grinding residues and metallic contamination are more easily removed by acids; very clean tungsten surfaces can be obtained by alkaline etching followed by acid etching.

An alkaline etchant can consist of molten NaOH containing 10 % $NaNO_2$. The melt temperature is 400 – 450 °C. Thin oxide films can also be removed by dipping tungsten in alka-

line solutions of $K_3[Fe(CN)_6]$. Other common alkaline etchants are 10 % solutions of NaOH or NH_3/H_2O_2. Acid etchants usually consist of $HNO_3/HF/H_2O$ mixtures. Other commonly used mixtures are $HNO_3/HF/CH_3COOH$ and $HClO_4/H_3PO_4/H_2O$.

Electropolishing. Tungsten can be anodically electropolished in a $K_2CO_3/KClO_3/NaOH/H_2O$ mixture. Another possible electrolyte is $CH_3OH/H_2SO_4/HF$.

4.9. Tungsten Coatings

Tungsten coatings are applied to metals, glass, ceramics, semiconductors, inorganic woven products, uranium carbide nuclear fuel granules, etc., for a large number of reasons, including the improvement of wear resistance, corrosion resistance, emissivity, and high-temperature properties [5]. The most important processes are:

Plasma Spraying (→Metals, Surface Treatment, Chap. 5.1.3.). This process is often used to apply very thick tungsten coatings (e.g., in the construction of engines and rockets), as the flame spraying process (used successfully with molybdenum) cannot be used with tungsten. The cathode material in the plasma burner is also tungsten.

Vacuum Vapor Deposition, Ion Sputtering, and Physical Vapor Deposition (PVD). In most of the usual coating processes, the substrate material must be raised to a high temperature, which usually has a detrimental effect on its mechanical properties. When tungsten is deposited by vacuum vapor deposition or ion sputtering onto a relatively cool substrate, these problems can be largely avoided. These coating methods are therefore very useful for metallizing semiconductors, ceramics, glasses, and also metals. The coatings are comparatively thin, but adhere well [34].

Deposition from the Vapor Phase, Chemical Vapor Deposition (CVD). Suitable readily vaporizable tungsten compounds include chlorides, fluorides [35], carbonyl compounds, and organometallic tungsten compounds. The carrier gas is hydrogen or a noble gas. Tungsten and tungsten alloys are applied in this way to, e.g., nuclear fuels (UC, UO_2), metallic substrates, and semiconductors. Small tungsten components are today manufactured by CVD.

Electrolytic Methods. Although there is an extensive patent literature [5] on the electrolytic deposition of tungsten coatings on metallic substrates, the method is not of practical significance. The production of tungsten coatings by diffusion, metallization, or cladding (including explosion cladding), has often been proposed, but has not become established as an alternative to other methods.

4.10. Production of High-Purity Tungsten Metal (99.999 – 99.9999 %)

The starting material is ammonium paratungstate (APT) of normal purity, but with uranium and thorium contents as low as possible. Important steps to high purity include:

1) Selective extraction of uranium and thorium [36]
2) Multiple crystallization of APT (giving a general reduction in the various trace impurities)
3) Working under clean-room conditions [38]
4) Electron beam zone melting [37], [39]

5. Tungsten Alloys

The addition of one or more elements or compounds to tungsten can improve its properties in a particular respect, or can combine the useful properties of tungsten with those of the additives. Depending on the additives, single-phase or two-phase alloys are produced. Powder metallurgy offers a simple route to the desired ratio of components, simply by mixing them. Of the large number of alloys described in the literature, only those of industrial importance are described here.

5.1. Single-Phase Mixed-Crystal Alloys

Tungsten – Molybdenum Alloys. Alloys with the composition Mo-10 W and Mo-30 W

have good corrosion resistance to molten zinc. In general, additions of tungsten increase the recrystallization temperature of molybdenum.

Tungsten – Rhenium Alloys. These have a higher recrystallization temperature than that of pure tungsten, a lower brittle – ductile transformation temperature, and higher high-temperature strength. They do not become brittle on recrystallization, and have superior welding properties. The alloying range of practical interest is 5 – 26 % Re.

The powder metallurgical method of production is from mixtures of tungsten and rhenium powder, or by coreduction by hydrogen of mixtures of yellow or blue oxide with ammonium perrhenate. The latter method ensures better uniformity.

High-temperature thermocouple elements, serviceable up to 2000 °C in protective gas atmospheres or in vacuum, are made from W- 5 Re or W- 26 Re wires.

The most important application area of W – Re alloys is in medical technology, where they are used in the manufacture of high-power rotating X-ray anodes, e.g., in computerized tomographic scanning equipment. The surface layer consists of a W-(3 – 10)Re alloy, while the body of the component is a Mo – W alloy, a Mo – Ti – Zr – O – C microalloy (TZM), or graphite [4], [33]. Compared with the pure tungsten anodes formerly used, the W – Re alloy can be operated at higher electron currents, allowing for shorter irradiation times. This is due to its greater stability to extreme alternating thermal stresses. The W – Re layer prevents roughening of the heated zones, and increases tube lifetime.

Tungsten – Tantalum Alloys. As with the molybdenum alloys, the only alloys of importance are those with high tantalum content. Developments have been principally aimed at pairing the good corrosion resistance and elasticity properties of tantalum with the superior strength and high-temperature strength of tungsten.

Ta-(7 – 8)W alloys are used in the manufacture of springs for use in strongly corrosive media [40], [41].

Ta-2.5 W is a corrosion-resistant construction material used in cases where the strength of pure tantalum is inadequate [42], [43].

Tungsten – Titanium Alloys. W-10 Ti is used as a sputtering target in the manufacture of microelectronic devices, such as VLSI or ULSI (very large or ultralarge scale integration), or DRAM (dynamic random access memory) chips.

5.2. Multiple Phase Alloys

Tungsten has excellent thermal properties and high density. However, for certain applications, its electrical and thermal conductivity, sensitivity to oxidation, and relatively poor machining properties are unsatisfactory. These limitations have led to the development of two-phase alloys in which the tungsten is the principal component. These are always produced by powder metallurgy.

Heavy Metals [44]. The term "tungsten heavy metal" means two-phase tungsten alloys of the type W – Ni – Fe (Ni 1 – 7 %, Fe 0.8 – 3 %, Mo 0 –4 %, magnetic) and W – Ni – Cu (Ni 1 – 7 %, Cu 0.5 – 3 %, Fe 0 – 7 %, nonmagnetic). The density varies between 17 and 19 g/cm^3, depending on the tungsten content.

They are produced by a powder metallurgical process involving liquid-phase sintering. Dense sintering takes place only slightly above the melting temperature of the eutectic mixture (1440 –1500 °C). As a result of the solubility of tungsten in the molten binder phase and the tendency of the interphase area of the system to decrease, recrystallization of the tungsten takes place, and hence a significant grain growth. The original mean particle size of the tungsten powder (3 – 5 µm) is increased in the sintered alloy (40 –100 µm). The structure consists of spherical tungsten grains that contain a few tenths of a percent of Ni and Fe in solid solution. These grains are embedded in a tough Ni – Fe – (Cu) matrix that contains ca. 4 % W in solution (Fig. 7).

In tungsten heavy metals, high modulus of elasticity and high electrical and thermal conductivity are combined with increased elongation and good machinability. This is due to the binder. Also, heavy metals have good absorption properties for γ- and X-rays, and are therefore used for radiation shielding. The properties of various heavy metal alloys are as follows [45]:

Density at 20 °C	17.0 – 18.5 g/cm^3
Modulus of elasticity	320 – 380 kN/mm^2
Shear modulus	125 – 160 kN/mm^2
Poisson's ratio	0.28 – 0.29
Hardness	
HV 10	270 – 470
HB 30	250 – 450
Tensile strength	660 – 1350 N/mm^2
Yield strength (0.2 %)	565 – 1300 N/mm^2
Fracture strain	2 – 15 %
Compressive strength	3500 – 5500 N/mm^2
Hot strength	
at 100 °C	560 – 730 N/mm^2
at 500 °C	340 – 610 N/mm^2
at 1000 °C	90 – 260 N/mm^2
Specific electrical resistivity	0.10 – 0.18 μΩ · m
Mean linear thermal coefficient of expansion, 20 – 800 °C	(5.22 – 6.45) $\times 10^{-6}$ mm^{-1} K^{-1}
Half-value thickness	
against ^{60}Co	8.5 – 9.7 mm
against ^{137}Cs	4.5 – 5.2 mm

Tungsten – Copper and Tungsten – Silver Alloys. Depending on the application, these can contain 20 – 50 % Cu or 10 – 80 % Ag. They combine the high hardness and high-temperature strength, the low welding tendency, and the excellent resistance to burning (by sparks and electric arcs) of tungsten with the high conductivity and good machinability of copper and silver, respectively.

Figure 7. Scanning electron micrograph of the fracture surface of non-sag tungsten after recrystallization, magnification 5000×

They are produced by a powder metallurgical process involving impregnation (infiltration). The tungsten powder, or a mixture of this with small amounts of the alloying element, is compacted and sintered at low temperature. The pores are then filled by infiltrating with a liquid phase. The amount of Cu or Ag required can be found from the "green" density (density of the compact prior to sintering). Infiltration can be by immersion, dipping, or flooding.

As the components W and Cu or Ag have practically no mutual solubility (pseudoalloys), no appreciable change in the particle size of tungsten takes place during infiltration, i.e., the tungsten skeleton approximately matches the particle size of the tungsten powder, though in densified form. The most important properties are listed in Table 4.

Non-Sag Tungsten (NS-W). This is a microalloy with metallic potassium. The technologically active alloying component, potassium, is present in trace concentrations (20 – 100 μg/g). The most important application is in the filaments of conventional incandescent lamps.

Non-sag tungsten wires have a so-called staple fiber structure (long, intertwined crystallites in an axial direction). This prevents the coiled wire from sagging when incandescent, and increases the creep strength at temperatures >2000 °C. The structure originates from small pores filled with metallic potassium, formed from larger potassium-filled bubbles by deformation (wire drawing) followed by heat treatment. The pores are arranged axially, i.e., in lines following the direction of deformation; they prevent slippage of dislocations and migration of grain boundaries on recrystallization. Grain growth is possible in the axial direction, and strongly inhibited in the radial direction.

The discovery of non-sag tungsten was accidental [47]. In the early 1920s, it was noticed that wire manufactured from tungstic acid calcined in special clay crucibles made by the Battersea Company of London had a more stable shape than wire from material calcined in standard crucibles. It was later reported that K, Si, and Al were picked up from the crucibles during the process. Since then, the oxide (formerly tungstic acid, but now blue oxide) is always doped with potassium silicate and the chloride or nitrate of aluminum.

On reduction of the oxide, finely dispersed phases of the doping elements K, Al, and Si (potassium aluminum silicates) are formed, and are then to some extent incorporated into the tungsten crystallites by overgrowth [48]. The doping elements mainly remain outside the powder particles, and are removed after the reduction process by washing with hydrofluoric acid. The final sintering evaporates any remaining dop-

∗ International annealed copper standard.

ing elements still adhering. The ternary silicate phase included in the powder particles dissociates at higher temperatures. The elements Si, Al, and O, which have small atomic radii, can diffuse through the tungsten crystal lattice and thus volatilize. The potassium atoms are too large, and, as potassium is insoluble in tungsten, remain behind as potassium-filled bubbles. These break up to form lines of very small bubbles on subsequent processing (Fig. 8).

Figure 8. Microstructure of a tungsten heavy metal W-7 Ni 3 Fe, magnification 250×

The amounts of doping elements added to the oxide are: K 2000 – 3000 μg/g; Al 200 – 400 μg/g; and Si 2000 – 3000 μg/g, of which the amounts remaining in the sintered microalloy are only 20 – 100 μg/g, <20 μg/g, and <10 μg/g, respectively.

In addition to their use in incandescent filaments, NS-W microalloys are used in halogen lamps, resistance wires for heating motor vehicle windows, and, owing to their excellent resistance to corrosion by molten metals, as containers and heating elements in aluminum vapor deposition plants.

Alloys with Oxide and Carbide Dispersions. Fine, homogeneously distributed dispersions of oxides of the elements Th, Y, Zr, La, and Ce increase the thermal conductivity and recrystallization temperature of tungsten and its alloys. The commercially most important alloy is thoriated tungsten (1 – 4 % ThO_2), although the radioactive thorium is replaced, where possible, by rare earth oxides. It is mainly used in welding electrodes. Thorium increases the thermal emission of electrons, and ensures a constant, stable electric arc. The dispersion-strengthened alloys W – Re – ThO_2 and W – Re – HfC have the highest high-temperature strength of all known metallic materials [36].

Porous Tungsten. This is not itself an alloy, but can become one, e.g., by impregnation. Tungsten components can be produced with 15 – 35 % porosity, and are then impregnated with Cu to give good machinability. After machining, the Cu is removed by vacuum evaporation.

Porous tungsten impregnated with alkaline earth oxides is used to make dispenser cathodes with reservoirs in high-power transmitter tubes. Ion thruster motors for space travel also use porous tungsten as ion sources for the high-temperature cesium vapor.

6. Uses

The uses of tungsten, its alloys, and compounds are extremely diverse. They can be divided into the following large groups (by consumption):

Hard metals	50 – 60 %
Steel	20 – 30 %
Tungsten metal and its alloys	6 – 20 %
Tungsten chemicals (for uses, see Chap. 9)	4 – 8 %

Hard Metals. These products represent by far the largest consumption of tungsten worldwide. With few exceptions, their main component is tungsten carbide (WC). Carbides, nitrides, or carbonitrides of Ti, Nb, Ta, and Hf can also be present as mixed crystal formers. The hard material phases are bonded together by a ductile metallic phase that surrounds them (cemented carbides), usually Co, more rarely Ni or Fe alloys.

The outstanding properties of the hard metals are their high hardness and wear resistance, especially at high temperatures, combined with good toughness properties. This unusual combination of properties is achieved by combining the hard and brittle carbide phase(s) with the ductile and deformable binder. By varying the carbide/ binder ratio, and by suitable choice of the carbide composition, the properties can be varied within wide limits. A further control parameter for certain properties is the microstructure, i.e., the grain size of the carbide phase(s), which can be controlled via the particle size of the powder used, the powder milling, and the sintering conditions.

The most important groups of applications of hard metals are:

1) Metal cutting tools (drilling, turning, milling)
2) Tools for processing wood and plastics
3) Drilling tools in mining and mineral oil and water drilling technology
4) Wear-resistant components in a wide range of machinery (a continuously increasing group with the widest diversification)
5) Elastically bonded abrasive materials

Steel. Tungsten is added to a very wide range of steels in a concentration of 1 – 18 %. It increases the hardness and wear resistance at high temperatures (carbide formation), resistance to thermal shock, and high-temperature properties. The main areas of use are in high-speed steels, high-temperature steels, and tool steels. The use of tungsten in steel is significantly greater in the People's Republic of China and the former Eastern Bloc countries, as high-speed steel is still used for many applications rather than hard metals, as in the West. In the United States, tungsten has mainly been replaced by molybdenum in high-speed steels.

Tungsten and Tungsten Alloys. This group represents the widest range of uses. It extends from everyday uses, e.g., the coil of an incandescent lamp or the contact tip of an automobile horn, to components of nuclear fusion reactors or ion drive motors in space probes. The reason for this range of uses lies in the many outstanding properties of tungsten:

High melting point
Low vapor pressure
High atomic number
Good electrical and thermal conductivity
High density and modulus of elasticity
Wide radiation band in visible light and good light yield
Good X-ray yield
Expansion coefficient comparable to those of glass and silica

The following list shows this versatility very clearly:

Lighting Technology
Incandescent lamps (NS-W)
Halogen lamps (NS-W)
Gas discharge lamps: Hg, Na vapor lamps (W)
Fluorescent tubes (W)
Xe short arc lamps (W, W – ThO_2, W – Re)

Electrical and Electronic Technology
Sputter targets in VLSI technology (W – Ti, high-purity W)
Transistors (W)
Diodes (W)
Electronic tubes (W, W – ThO_2, porous W with Ba or ThO_2)
Thyristors (W)
Switch contacts [W, W – Cu, W – Ag, W – Fe – Ni – (Cu)]
Heat sinks (W – Cu)

High-Temperature Technology (furnace construction, nuclear energy, thermal power stations)
Structural components (W)

Walls of fusion reactors (W, W – Re – ThO_2, W – Re – HfC)
Construction components in the plasma space in magnetohydrodynamic electricity production (W, W – Cu)
Thermocouple elements (W/WRe, W/Mo, W/Ir, W/graphite)
Heating elements (W)

Vacuum and Plasma Metallization, Welding, Spark Erosion
Nozzles (W – ThO_2)
Electrodes [W – ThO_2, W – Ag, W – Fe – Ni – (Mo)]
Welding electrodes (W – ThO_2, W – LaO_2, W – CeO_2, W – ZrO_2, W – Y_2O_3)

X-Ray and Radiation Technology, Medical Technology
Anodes (W)
Rotating anodes (W – Re)
Containers for radioactive materials (W – Fe – Ni)
Components for radiation shielding, e.g., collimators in computer tomography scanners [W – Fe – Ni – (Cu)]

Machinery and Motor Construction
Governor balance weights, counterbalance weights, flywheel weights and other weights, e.g., in Formula 1 racing cars [W – Fe – Ni – (Cu)]

Chemical Industry
Electrodes, nozzles, crucibles (W)
Construction materials (W – Mo)

Space Travel
Rocket nozzles (W, W – Ag)
Space nuclear reactors (W – Re)
Thermionic converters (porous W, CVD-W, W – Re)
Ionic reactive thrust motors (porous W)
Structural components (tungsten fiber-reinforced niobium matrix composites, superalloys, Al, Ti)

Armaments
Armor piercing shells, armor plating, scatter grenades, shaped charge liners, couterweights in tanks, nozzles for air-to-air rockets, gas rudders (W – Fe – Ni, W – Cu, W – ThO_2)

Aircraft
Aircraft nose counterweights (W – Fe – Ni)
Turbine blades of fiber-reinforced nickel-based superalloys (W – Re – ThO_2 and W – Re – HfC fibers)

Laser Technology
Cathodes (porous W/barium aluminate)
Components of gas lasers (W – Cu)

7. Analysis

7.1. Raw Materials

The determination of the tungsten content of ore concentrates and scrap is very important, as the price is calculated from this. Sampling procedures are also extremely important, as the high density of tungsten can easily lead to segregation [49]. Determination of tungsten itself is almost exclusively carried out by X-ray fluorescence analysis [50]. Thus, matrix effects are compensated for by dissolution and dilution, and by the addition of an internal standard. Molten lithium tetraborate is widely used as a solvent, with tantalum pentoxide as an internal standard. Matrix corrections are carried out with computer programs.

7.2. High-Purity Intermediate Products, Tungsten Powder, and Compact Tungsten Metal

In these materials, it is not sufficient to determine the tungsten. In any case, especially in the metallic state (99.97 – 99.98 % W) this would be far too inaccurate. Here, it is important to measure trace impurity contents. In all these products, the specifications applicable are very rigorous, setting maximum acceptable upper limits for concentrations of individual elements. For industrial tungsten and its high-purity precursor materials, these are all in the μg/g range, the maximum tolerable level for most elements being 10 μg/g. Exceptions include Mo (50 μg/g), Si (20 μg/g), and H (1 μg/g).

Routine determination of trace elements is mainly carried out by the following methods:

Flame atomic absorption spectrometry
Graphite tube atomic absorption spectrometry

Inductively coupled plasma optical spectrometry
Photometry
Vacuum fusion hot extraction (H, N)
Carrier gas hot extraction (O)
Ignition in oxygen combined with IR spectrometry (C)

Up-to-date literature on this topic is rare, as improved and refined analytical methods are increasingly regarded as industrial secrets. The determination of metallic trace impurities is described in [51], [52], and of nonmetallic trace impurities in [53–55].

Large samples are always used. The result therefore always represents a mean value. Also, these analyses give no information on the distribution of a trace element and its state of bonding in the compact metal [56], [57]. It is well known that impurities can exist in various forms and states of combination in metals (dissolved interstitially or as mixed crystals, as precipitates in the crystal or at grain boundaries, etc.). This knowledge is often important for subsequent treatment processes or for the final properties. Topochemical analytical methods are also used:

Scanning electron microscopy coupled with energy or wavelength dispersive X-ray spectrometry
Auger electron spectroscopy
Auger microprobes
Ion beam microprobes
UV and X-ray photoelectron spectrometry, etc.

These techniques are not used routinely, mainly because of their cost, but for special applications and in research.

Heterogeneous impurities represent a special case (though often widely occurring) of particular importance in powder metallurgy. These impurities are small foreign particles present in a certain statistical distribution alongside the matrix particles. In most cases, they are due to mechanical abrasion or corrosion of production equipment. They can become concentrated in furnaces by vaporization, and can then end up in the material. Organic materials can also be present in the powders, e.g., fibers from filter cloths, packing materials, or plastic films. The various types of heterogeneous impurities, their effects, and their analytical determination are described in [58–61].

The presence of this type of heterogeneous impurity can lead to very serious material defects on powder metallurgical processing. Unlike molten metallurgical processes, where small foreign particles can dissolve in the homogeneous melt or slag, and hence cause very little change to the composition, the sintering of a compact can still leave locally high concentrations of a foreign element. Consequently, many kinds of defects can occur, e.g., empty or filled pores, porous zones, zones with completely changed material properties, etc., leading to fractures and cracks on subsequent processing. Fine wires and thin sheets are therefore extremely sensitive to heterogeneous impurities.

In the characterization of tungsten powder, physical analysis is important as well as chemical analysis [62]. Typical powder characteristics include:

Mean grain size (Fisher sub-sieve sizer, ASTM No. 430-1970)
Morphology, heterogeneity (scanning electron microscopy, SEM)
Particle size distribution (sedimentation, laser scattering, ultracentrifuge)
Bulk, tapped, and pressed density
Specific surface area (BET method)
Degree of agglomeration

7.3. Trace Elements in High-Purity Tungsten Metal

In high-purity tungsten metal, levels of trace elements are in the ng/g range. There are therefore special analytical requirements:

Working in a clean-room laboratory
Prevention of any other contamination
Correct calibration, etc.

Comparisons between various methods and laboratories show clearly that in trace analysis of this kind the results can have considerable scatter [63], [64]. The analytical techniques are always very complex and expensive, the most important being:

Glow discharge mass spectrometry
Secondary ion mass spectrometry
Isotope dilution mass spectrometry
Trace matrix separation combined with inductively coupled plasma mass spectrometry

Very significant improvements in this type of analysis have been achieved [38].

8. Ferrotungsten and Related Alloys

8.1. Composition

Ferrotungsten. Commercial ferrotungsten is a tungsten – iron alloy containing at least 75 wt % W, and having a very fine-grained structure and a steel-gray appearance. It is supplied in 80 – 100 mm lumps in accordance with DIN/ISO standard specifications. Special sizes can be produced by further size reduction to suit customers' requirements. The standardized compositions are listed in Table 5 [65].

The binary phase diagram for Fe – W is shown in Figure 9. The phases Fe_7W_6 (μ) and FeW (δ) exist close to the edge phases. However, ferrotungsten occurs in the equilibrium state only after prolonged high-temperature treatment. Therefore, in commercial ferrotungsten, the phase Fe_2W (λ) should still be present alongside the δ-phase. The melting temperature of ferrotungsten containing ca. 80 % W is very high, the liquidus temperature being >2500 °C and the solidus temperature ca. 1640 °C. The density of ferrotungsten is 15.4 g/cm^3.

Tungsten Melting Base (TMB). The term "tungsten melting base" refers to alloys produced from secondary raw materials. These can have various compositions, depending on the type of recycled material used. Typical analyses are listed in Table 6. The alloys are supplied as granulated material with grain size <10 mm.

8.2. Uses

Ferrotungsten and Tungsten Melting Base. Ferrotungsten and tungsten melting base are mainly used as alloying materials in the steel industry as they dissolve more readily than pure tungsten in molten steel, owing to their lower melting points, and are also cheaper.

Tungsten additions increase the hardness, yield strength, and ultimate tensile strength of the steel without reducing the elongation, area reduction on breaking, and notched bar fracture toughness [70].

In steel, tungsten forms stable carbides that increase hot strength and wear resistance. Tungsten-containing alloys are therefore mainly used in the production of tool steels, especially high-speed steels [71].

High-speed steels (HSS) represent the main application area for ferrotungsten. These steels are highly alloyed with tungsten, molybdenum, vanadium, and chromium. After the correct heat treatment, they have high hardness and wear resistance, and are mainly used for machining at high cutting rates and temperatures up to 600 °C. The alloying elements and the carbon form hard, wear-resistant carbides in a matrix with good hardness retention properties. The standard high-speed steels specified in DIN 17 350 contain 6 – 18.5 % tungsten [72].

Other Tungsten-Based Master Alloys. Other master alloys, used especially in the production of nickel-based superalloys, include Ni – W, complex nickel-based alloys containing Cr, Ta, and Mo [69], and cobalt – chromium – tungsten master alloys for wear-resistant materials and protective coatings [73] (→ Cobalt and Cobalt Compounds).

The master alloys for superalloys must be produced from very pure raw materials. They are melted in vacuum induction furnaces, and are cast and cooled under vacuum. The delivered form is small lumps (<50 mm) or powder (<0.3 mm). Some typical compositions are listed in Table 6.

8.3. Production

8.3.1. Ferrotungsten

The raw materials used for ferrotungsten production are rich ores or concentrates containing the minerals wolframite, hübnerite, ferberite, and scheelite. "Synthetic scheelite", a precipitated calcium tungstate, is also used.

These raw materials contain tungsten in the form of WO_3, which can be relatively easily reduced either with carbon or silicon and/or aluminum. Reduction with magnesium and calcium is also possible, but is of no industrial importance for cost reasons. Figure 10 shows the effect of temperature on the oxygen potentials of metal oxides. Although tungsten forms carbides with carbon, the formation of tungsten carbide in the finished product can be virtually prevented by suitably controlling the CO : CO_2 ratio, so that a low-carbon ferrotungsten with a maximum carbon content of 1 % is produced. Tungsten oxides

Table 5. Specifications of the composition of ferrotungsten ∗, DIN 17 562 and ISO 5450 [65]

	% W		% C max.	% Al max.	% Sn max.	% As max.	% Sb max.		% Mo max.

Figure 9. Binary phase diagram of the Fe – W system [66]

Figure 10. Effect of temperature on the oxygen potentials of oxides [74]

are reduced in preference to iron oxides, so that ferrotungsten with a high tungsten content can be produced, even if the ore has a high FeO content.

Thus, ferrotungsten can be produced by carbothermic reduction in an electric arc furnace or by metallothermic reduction with silicon and/or aluminum.

The carbothermic or silicocarbothermic method is preferred for cost reasons. Moreover, higher impurity contents (tin and arsenic) can be tolerated in the raw materials.

When high levels of arsenic and tin are present in the concentrates, these can be vaporized by roasting in rotary tube furnaces.

8.3.1.1. Carbothermic Production

Because of the high melting point of ferrotungsten, the so-called solid block melting process is normally used, as tapping off is not possible at the furnace temperatures that are required.

In this process, the ferrotungsten accumulates in the hearth of the furnace vessel, which is constructed in sections. After the desired weight has been produced, the furnace lining is removed

and the metal ingot can be removed after cooling. The solid block is cleaned, crushed, and sorted. The cleaned-off material and skin of the ingot are returned to the furnace for remelting.

The use of several melting vessels enables the process to be semicontinuous.

The process is usually operated in two stages, as an excess of tungsten ore is used in the ingot melting process (refining stage), producing a WO_3-rich slag that must be processed in a second (reduction) stage to give ferrotungsten with a low W content and a low-WO_3 slag.

The low-W ferrotungsten is reused in the refining stage. The slag, which contains $<1\,\%$ WO_3, can be dumped. The flow diagram of this two-stage process is shown in Figure 11 [75].

In the three-phase electric arc furnaces usually used today, the pitch circle diameter of the electrodes is small to ensure adequate energy concentration. Typical furnace data for a three-phase electric arc furnace for the production of FeW 80 are [76]:

Power	2000 – 3000 kV · A
Refractory lining	monolithic rammed carbon
Electrode material	
refining stage	graphite
reduction stage	Söderberg
Energy consumption per tonne FeW	7500 – 8500 kW · h
FeW ingot weight	11 – 12 t

The electric arc furnaces are provided with waste-gas purification plants both for environmental reasons and to realize the value of the WO_3 in the flue dust. This dust, enriched in arsenic and tin vaporized from the concentrates, is usually added to the reduction stage or processed in special batches. The resulting secondary dust must either be chemically processed to obtain tungsten compounds or disposed of as a special waste if it cannot be sold.

Tungsten yields of 97 – 98 % can be obtained in the solid block process.

8.3.1.2. Carbothermic and Silicothermic Production

In 1937, V. N. Gusarov developed a continuous process for the production of ferrotungsten containing ca. 75 % W. This was used in the former Soviet Union and the former Czechoslovakia [77], [78]. It is presumably used in the Czech Republic.

This metallurgically interesting process is carried out in three successive stages in a three-phase electric arc furnace lined with magnesite. Of the oxygen in the WO_3, 60 % reacts with carbon and 40 % with silicon (as ferrosilicon containing 75 % Si). In the first stage, ferrotungsten (75 % W) is produced by substoichiometric carbon reduction. This ferrotungsten is formed in a pasty consistency under a WO_3-rich slag, and can be scooped out with ladles. Details of the individual processes are as follows:

Stage 1. Reduction of tungsten ore concentrates by carbon under a WO_3-rich slag (10 – 16 % WO_3, 26 – 28 % FeO, 15 – 17 % MnO), and scooping out the ferrotungsten (e.g., 73.3 % W, 0.4 % Mn, 0.43 % Si, 0.05 % P, 0.06 % S, 25.2 % Fe).

Stage 2. Reduction of the WO_3-rich slag with FeSi 75 and addition of scrap iron (to reduce the tungsten content of the ferrotungsten produced). Tapping off the low-WO_3 slag (e.g., 0.3 % WO_3, 20.8 % MnO, 51 % SiO_2, 2.7 % FeO, 3.6 % Al_2O_3, 21.1 % CaO). The metal, with a reduced tungsten content (54 – 70 % W, 3 – 8 % Si, 1 – 2 % Mn) remains in the furnace.

Stage 3. Refining of the low-tungsten metal by adding tungsten concentrates. A WO_3-rich refining slag (18 – 25 % WO_3) is formed, and the tungsten content of the metal increases.

The advantage of the process is the continuous method of operation; thus the furnace can be operated for considerably longer periods without interruption for relining than in the solid block process. A further advantage is the lower energy consumption, i.e., ca. 4000 kW · h per tonne of ferrotungsten. The tungsten yield is 98 %, approximately the same as for the solid block process.

Disadvantages include the heavy labor of the scooping operation and the accumulation of some of the ferrotungsten in a “furnace sow” or “salamander”. This ferrotungsten can be retrieved only after furnace relining, and is recovered as product after remelting.

Figure 11. Carbothermic production of ferrotungsten [75]

8.3.1.3. Metallothermic Production

Tungsten oxide can be reduced by silicon and/or aluminum (see Fig. 10). Compared with carbothermic reduction, metallothermic production of ferrotungsten requires purer raw materials, as the reactions proceed very rapidly, and the impurities are chemically reduced as well as the raw materials. In this process, about 50 % of the tin and arsenic present, most of which would be vaporized during the longer carbothermic process, end up in the ferrotungsten.

The tungsten concentrates in finely divided form are mixed with coarsely powdered aluminum and silicon. Pure silicon or ferrosilicon cannot be used, as these would not give a selfsustaining reaction, the heat evolved being insufficient to melt the ferrotungsten and slag formed. Aluminum and silicon in the ratio 70 : 30 are therefore used.

The reaction mixture is charged into a refractory-lined furnace vessel and preheated to 400 –500 °C. The preheating can be omitted if Fe_2O_3 and Al are mixed into the reaction mixture as a booster.

The reaction is started at the top by igniting initiators, which are mixtures of, e.g., BaO_2 and aluminum powder. A purely aluminothermic mixture burns completely in a few minutes, but silicothermic – aluminothermic mixtures react more slowly. After cooling, the furnace vessel is removed, and the blocks of metal and slag are separated. This method produces ferrotungsten ingots of 700 – 2000 kg. The metal ingot is cleaned, crushed, and sorted. Pieces with adhering slag are sent back for remelting.

The metallothermic production process has lost much of its importance owing to the high costs of the aluminum and silicon reducing agents, and the necessity for using pure and therefore expensive raw materials.

The process is suitable only for special customer requirements, and for operations which also produce other alloys by the aluminothermic principle.

Advantages of the process include the simple, low-cost plant, and the minimal tying-up of materials resulting from the short processing time. The tungsten yield is ca. 96 %.

M. Riss and Y. Khodorovsky have described the electroaluminothermic production of ferrotungsten from scheelite [78]. The reaction time is extended by melting in an electric arc furnace, and separation of the metal from the slag is improved.

8.3.2. Production of Tungsten Melting Base and Tungsten Master Alloys

During World War II, melting base alloys for the production of high-speed steels were developed and marketed by the London and Scandinavian Metallurgical Company (LSM). They were produced from tungsten hammer scale, grinding wheel swarf, and other waste products by reductive smelting in electric arc steel furnaces.

A similar recycling process is today operated by the Treibacher Chemische Werke. Here, the tungsten-containing waste is pretreated (degreased, etc.), melted in an electric arc furnace (7.2 MV · A) to produce tungsten melting base (TMB), and is then granulated. At this plant, which is also used for other ferroalloys, the TMB production rate is ca. 1000 t/a in the late 1980s. The product specifications are listed in Table 6 [67], [79].

J. Becvar has described a process operated in the Czech Republic [68]. Tungsten-containing wheel swarf is first degreased and dewatered, and is then melted with other scrap in an electric arc furnace to give a so-called Darby melt, which is used as a master alloy for high-speed steel. A typical composition is given in Table 6. The

process appears favorable, as other alloying elements in the scrap, e.g., chromium and vanadium, are also recovered.

Other master alloys used for superalloys also require very pure raw materials. The alloys are melted in vacuum induction furnaces, tapped off, and cooled under inert gas (argon). Some examples of the alloys produced by the Gesellschaft für Elektrometallurgie mbH (GfE) in Nuremberg are listed in Table 6. These are supplied either as small lumps or powder [72].

9. Compounds

9.1. Tungsten Chemistry

Tungsten occurs in all oxidation states from -2 to +6 inclusive, the most important being +6. Valencies between -2 and +1 exist only in organometallic compounds and compounds with π-acceptor ligands. In the lower valencies, tungsten forms bases (sometimes unstable), but in the higher valencies it forms very stable acids.

Tungsten combines with most elements and with a large number of inorganic and organic ligands. The highest coordination number is 8, and the most important donor atoms are O, N, S, and the halogens. Tungsten has a very marked tendency to form polymeric compounds.

9.2. Aqueous Solutions of Tungsten

This chemistry is extremely complex [80], [81], as the tungstate anion exists in monomeric form only in strongly alkaline solutions. In mildly alkaline solution, the tungstate anions begin to polymerize, and this progresses with decreasing pH. Below pH 1, sparingly soluble tungsten oxide hydrate (tungstic acid) precipitates. Various degrees of polymerization (isopolytungstates, metatungstates, paratungstates, etc.) are favored as the pH changes [82]. Other parameters influencing the polymerization include concentration, temperature, and time. Time plays an important role in reactions that proceed slowly. Thus, the properties of mildly acid or almost neutral solutions of tungsten change markedly after long periods of storage (a process often referred to as aging). Foreign ions also influence various polymerization reactions. Ammonium ions favor polymerization, even at higher pH values. This is why $(NH_4)_2WO_4$ cannot be crystallized from aqueous solution (it always forms APT), but only from tungstic acid and liquid ammonia. Anions such as phosphate, silicate, arsenate, etc., copolymerize with tungstates to form heteropolytungstates which usually have a higher degree of polymerization than the isopolytungstates stable at the same pH. Several isopolytungstates group around the central heteropolyanion.

Fluoride, sulfide, and peroxo anions have a depolymerizing effect, as these replace O atoms on the W [80]. The substitution of several O atoms by organic compounds with two or more donor atoms leads to the formation of numerous chelate complexes, and hence to depolymerization [80].

9.3. Intermetallic Compounds

There are a number of compounds of tungsten with the elements Al, Be, Co, Ni, Fe, Zr, Hf, Ir, Os, Re, Ru, and Tc which can play a positive or negative role in the metallurgy of tungsten alloys. A comprehensive review of the literature on this subject can be found in [4].

9.4. Compounds with Nonmetals

9.4.1. Tungsten – Boron Compounds [4], [83]

The following compounds are known: W_2B, WB, W_2B_5, and WB_4. They are prepared by sintering the elements, from the oxides in an aluminothermic reaction, or by deposition from the gas phase. They are hard, brittle, crystalline, and electrically conducting, and are of no industrial importance.

9.4.2. Tungsten – Carbon Compounds [4]

There are three carbides (Table 7): W_2C, WC, and the cubic high-temperature phase α-WC_{1-x}.

Table 7. Physical properties of tungsten carbides

	mp, °C	Crystal system	Density, g/cm^3
W_2C	2770	hexagonal	17.2
WC	>2600 (decomp.)	hexagonal	15.6
α-WC_{1-x}	ca. 2750	cubic	

Production. The carbides are formed from tungsten or its compounds by reaction with carbon or carbon compounds. The most important industrial process is the reaction of tungsten metal powder with carbon black or graphite at 900 – 2200 °C. The reaction of WO_3 with carbon is of less importance, as it is difficult to control the carbon balance.

Industrial Importance. WC is quantitatively the most important tungsten compound because of its hardness. It is also used as a reforming catalyst.

W_2C, like WC, is present in the carbide melt used for "hard facing".

Mixed-crystal carbides such as WC – TiC (50 : 50) and WC – TiC – Ta(Nb)C (very variable composition) are widely used in hard metal production.

The η-carbides, of composition Co_6W_6C and Co_2W_4C to Co_3W_3C, and analogous compounds with Fe occur as intermediates in tungsten-containing steels and in special grades of hard metal.

Tungsten Hexacarbonyl $W(CO)_6$ [84]. This can be produced from W + CO or from WCl_6 + CO + Al. It is a white, crystalline substance that decomposes at 150 °C and is soluble in organic solvents, e.g., CCl_4. It is used as a catalyst in organic syntheses.

9.4.3. Tungsten – Silicon Compounds [4], [83–85]

The following compounds are known: WSi_2, W_5Si, W_3Si_2, W_2Si_3, and W_5Si_2. They are produced by heating the elements together. They are hard and stable to 900 °C. Tungsten silicide sputter targets are used in microelectronics to produce WSi_x films because of their exceptional characteristics and their thermal and chemical stability.

9.4.4. Tungsten – Group 15 Compounds

Tungsten – Nitrogen Compounds [84]. The following compounds are known: W_2N and WN. They are not formed by reaction of the elements, but by heating tungsten in ammonia gas. They are of no industrial importance.

Tungsten – Phosphorus Compounds [4], [85]. The following compounds are known: WP_2, WP, W_2P. These can be synthesized from the elements. They are of no industrial importance.

Tungsten – Arsenic Compounds [4]. The following compounds are known: WAs_2, W_2As_3. Synthesis is from the elements. They have no industrial importance.

9.4.5. Tungsten – Oxygen Compounds

Oxides [84], [86]. In the W – O system, there are not only the stoichiometric oxides WO_3, $WO_{2.9}$, $WO_{2.72}$, WO_2, but also nonstoichiometric structures that represent the ordered or partially ordered defect structures of the oxygen-rich oxides, in which the central W atom is octahedrally surrounded by six oxygen atoms. In WO_3, neighboring octahedra are in contact only at the corners. With increasing oxygen deficiency (reduction, conversion to lower oxides), common edges and surfaces are progressively formed.

Tungsten trioxide, WO_3, is formed on strongly heating tungstic acid or APT in air. It is yellow, but even a small oxygen deficitency leads to greenish colorations. There are several crystallographic modifications which differ structurally from each other (variable distortion of the WO_6 octahedra). Commercial WO_3 (density 7.29 g/cm^3) is monoclinic at room temperature. Heating to just below 700 °C leads to orthorhombic WO_3, and above this temperature

to the tetragonal form. It begins to vaporize appreciably below its melting point (1473 °C). It is much more volatile in the presence of water vapor. WO_3 is soluble in alkaline solutions and melts.

$WO_{2.9}$ ($W_{20}O_{58}$) is bluish-violet, and occurs as an intermediate product during the reduction of WO_3 with hydrogen. It can be prepared by the reduction of WO_3 by moist hydrogen (e.g., 500 – 550 °C, water vapor pressure 60 kPa). It is a component of commercial blue oxide.

$WO_{2.72}$ ($W_{18}O_{49}$) is reddish-violet, and above 570 °C occurs as a characteristic needle-shaped intermediate product of WO_3 reduction. It is prepared in the pure state by reducing WO_3 with moist hydrogen (e.g., 800 °C, water vapor pressure 80 kPa). It can be present at low concentrations in industrial blue oxide.

Tungsten dioxide, WO_2, is chocolate brown in color, and is also an intermediate product of the reduction of tungsten compounds. It forms monoclinic crystals with a distorted rutile structure, and is therefore structurally very different from the higher oxides. The pure material is produced by reduction of WO_3 with moist hydrogen (e.g., 900 °C, water vapor pressure 50 kPa).

β-Tungsten, W_3O, [87], [88], is a gray or black substance produced at low reduction temperatures, usually during the reduction of doped tungsten oxides. It has a cubic A_{15} structure, and was first described as an allotropic modification of the metal, later as the suboxide W_3O. It is now thought that it is a metastable metallic phase stabilized by oxygen. It is stabilized by a series of other foreign elements, e.g., K, Be, P, B, As, and Al. It occurs as a characteristic intermediate product in the reduction of tungsten oxides doped with K, Al, and Si. Pure β-tungsten (by X-ray analysis) can be prepared by reduction of a thin layer of $W_{20}O_{58}$ powder in dry hydrogen at 500 – 600 °C.

Oxide Hydrates. $WO_3 \cdot H_2O$ or $WO_2(OH)_2$ [89] occurs as a monomeric gaseous compound during the industrial reduction of tungsten oxides with hydrogen at >600 °C. It is formed by the reaction of the oxides with the water vapor formed during the reduction, and is the substance on which the chemical vapor transport of tungsten depends.

Tungstic Acids [4], [84], [90]. H_2WO_4 is formed when a hot alkali metal tungstate solution is acidified with a strong acid. It is a yellow powder, very sparingly soluble in water and acids, but very soluble in alkaline media.

White tungstic acid is obtained by precipitating in the cold and reversing the order of addition. It corresponds to the composition $WO_3 \cdot x\,H_2O$, where $x \approx 2$.

If tungstic acids are dried at <300 °C, the orange-yellow hemihydrate $2\,WO_3 \cdot H_2O$ is obtained.

Tungstic acid was formerly the most important high-purity intermediate product used in tungsten production, but has now been replaced by APT.

Tungstic acid in a highly pure form is today produced from APT by treatment with strong acids, and is used in the production of very fine tungsten powder and various tungsten-based chemicals.

Tungstates [4], [84], [91]. These are formed by most metal cations (e.g., Na_2WO_4, $NiWO_4$, Cr_2WO_6, ZrW_2O_8). The structure of the tungstates is mainly determined by the size of the metal cation. Tungstates with large bivalent cations ($\gg$0.1 nm) have the scheelite structure, and those with smaller ions (<0.1 nm) the wolframite structure. Apart from the alkali metal and magnesium tungstates, these are all sparingly soluble in water. All the most important ores are tungstates.

Sodium tungstate crystallizes with two molecules of water of crystallization. Aqueous solutions are used as heavy liquids, in fuel cells, for flame-resistant and antistatic textiles, in cigarette filters, and as corrosion inhibitors for steel. Anhydrous sodium tungstate is obtained by melting WO_3 with sodium hydroxide or carbonate.

Calcium tungstate fluoresces under ultraviolet light, a phenomenon which is utilized when prospecting for scheelite deposits. Calcium tungstate is used in the production of phosphors for lasers, fluorescent lamps, oscilloscopes, luminescent dyes, scintillation counters, X-ray screens, etc.

A wide range of tungstates are used in the ceramic industry, in catalysts, and in pigments.

Polytungstates. The tendency of tungstate ions to polymerize in aqueous solution has already been referred to. The degree of polymerization increases with decreasing pH until tungstic acid is precipitated at pH 1. Other anions, e.g., arsenate, phosphate, silicate, can be incorporated into these highly polymeric ions. According to whether the polyanions are composed only of tungstate or also include foreign ions, they are referred to as isopolytungstates or heteropolytungstates.

Isopolytungstates can have various preferred degrees of polymerization, as mentioned above [82]. The most industrially important compound in this class is APT, the most widely used high-purity raw material in the tungsten industry.

Ammonium metatungstate is produced either with the aid of ion exchangers or by electrodialysis, and, owing to its high solubility in water, is used for impregnating carriers (e.g., aluminum oxide) in the production of catalysts.

Sodium metatungstate is used as a heavy liquid when drilling for oil.

Amine Tungstates [82], [92], [93]. Organic amines form water-insoluble ion associate complexes with isopolytungstates. Complex long-chain amines ($C_8 - C_{10}$) are used as reagents in the industrial solvent extraction of tungsten. Complexes with short-chain amines (ethylenediamine, propylamine, etc.) show autoreductive and autocarburizing properties on heating. This is of interest for the production of finely powdered W or WC, which can be obtained from the precursor in a single-step process.

Heteropolytungstates. There are over 30 elements known to form the central anion in these compounds. Typical properties independent of the central heteroatom include high relative molecular mass (>3000), high degree of hydration, and high solubility in water and organic solvents. A summary of possible structures and compositions can be found in [84].

One of the most industrially important compounds in this group is $Na_3PW_{12}O_{40} \cdot x\,H_2O$ [94], [95]. This has many uses: for fixing and oxidizing in photographic processes; as an additive in electroplating; for waterproofing plastics, adhesives, and cement; in the production of organic pigments; for the surface treatment of skins; as an antistatic agent for textiles; for printing and paper dyes; for coatings; wax pigments; steel passivation; and as a catalyst in the organic chemical industry.

Tungsten Bronzes [4], [84], [91]. These are well-defined though nonstoichiometric compounds with the general formula M_xWO_3, in which x is between 0 and 1; M represents a metal cation, H^+, or NH_4^+. The name is derived from the metallic luster and intense colors (golden yellow to blue-black) of these compounds. The bronze character is determined by the amount of metal in the structure. With high values of x, interaction between the metal ions leads to the formation of metallic bonds. The stability of the bronzes is determined by the size of the metal ions. Stability decreases as the ionic radius decreases. Small metal ions, e.g., Si and Ge, do not form bronzes. Owing to the oxygen deficit, these compounds are electrical semiconductors or conductors. The sodium bronzes for which the Na/WO_3 ratio is >0.3 have a positive temperature – resistance coefficient, and vice versa.

The bronzes are produced:

1) By partial reduction of the corresponding tungstates
2) By electrolytic reduction
3) By the reaction in the fused or solid state of $WO_3 - WO_2$ mixtures with metal compounds

Tungsten bronzes are used as colored pigments, catalysts, e.g., for the oxidation of CO, and in fuel cells. Electrodes made of La_xWO_3 are used in sensors for the potentiometric determination of dissolved oxygen.

Hydrogen and alkali metal bronzes are used as electrochromic coatings for so-called dynamic glasses. Application of an electrical potential causes migration of the ions (H^+, Na^+) into or out of the coating, thereby changing the properties of the glass from transparent (oxidic) to reflecting (metallic due to bronze formation). The only practical application of this so far is in electrochromic sunglasses.

9.4.6. Tungsten – Chalcogenide Compounds

Tungsten – Sulfur Compounds [4], [84], [96], [97]. The following compounds are known: WS_2, WS_3. Tungsten disulfide is of industrial

importance. It is black, forms hexagonal or rhombic crystals, and can be synthesized from the elements. It is used as a catalyst for the desulfurization of mineral oil, and as an oil-soluble lubricant under extreme conditions (pressure, temperature, vacuum).

Tungsten – Selenium Compounds [4], [97]. The following compounds are known: WSe_2, WSe_3. The diselenide can be synthesized from the elements, and is used as an oil-soluble lubricant.

Tungsten – Tellurium Compounds [4]. WTe_2 is known, but is of no industrial importance.

9.4.7. Tungsten – Halogenide Compounds

Tungsten – Fluorine Compounds [4], [84]. The following compounds are known: WF_6, WF_5, WF_4, WOF_4, WO_2F_2, WOF_2. Only the hexafluoride is of industrial importance, being used to produce CVD tungsten. It can be produced by the reaction of tungsten hexachloride with hydrogen fluoride, or by direct combination of the elements at 350 – 400 °C. The boiling point is 17.5 °C. The colorless gas is soluble in organic solvents, and is sensitive to moisture (hydrolysis).

Tungsten – Chlorine Compounds [4], [84]. The following compounds are known: WCl_6, WCl_5, WCl_4, WCl_2, $WOCl_4$, WO_2Cl_2, $WOCl_3$, $WOCl_2$. Two of these are of industrial importance:

Tungsten hexachloride is a crystalline blue-black compound (*mp* 275 °C, *bp* 346 °C). It is obtained by direct combination of the elements at 600 °C. It is soluble in carbon disulfide and organic solvents, and is hydrolyzed by water. It has a wide range of uses in catalysis.

Tungsten oxytetrachloride forms red crystals (*mp* 211 °C, *bp* 327 °C), and is soluble in carbon disulfide and benzene. It is produced by the reaction of sulfuryl chloride with WO_3. It too has a wide range of uses in catalysis.

Tungsten – Bromine Compounds [4], [84]. The known compounds, which are of no industrial importance, are: WBr_6, WBr_5, WBr_4, WBr_3, $WOBr_4$, WO_2Br_2, $WOBr_2$, $WOBr_3$.

Tungsten – Iodine Compounds [4], [84]. The known compounds, which are of no industrial importance, are: WI, WI_3, WI_2, WO_2I_2, WOI_2, WO_2I, WOI_4.

10. Tungsten in Catalysis [69], [98–100]

Tungsten, both in metallic form and in a wide range of compounds, is used as a catalyst or catalyst component in a large number of chemical processes.

In the form of a metallic alloy with Ni, Co, or Rh, sometimes in the form of a sulfide, and sometimes on aluminum oxide carriers, it can catalyze the reaction of CO with H_2, and also hydrotreating, hydrocracking, reforming, and hydrodesulfurization reactions.

The following oxides are used as catalysts:

WO_3 is used in colloidal form for the photocatalytic reduction of organic compounds.

$W_{20}O_{58}$ catalyzes hydrogenation, dehydrogenation, hydroxylation, epoxidation, etc.

Mixed oxides of WO_3 with TiO_2 and/or V_2O_5, Al_2O_3, or SiO_2 have a wide range of uses, e.g., as DENOX catalysts for exhaust gas cleaning in thermal power stations, hydrogenation, aldol condensation, ring opening reactions, dimethyl sulfoxide synthesis, etc.

Of the halides, the compounds WCl_6 and $WOCl_4$ play a very important role in organic chemistry as catalyst components, e.g., in association with organometallic compounds such as $AlCl_2(C_2H_5)$, $Sn(C_6H_5)_4$, $Sn(CH_3)_4$, $Sn(C_4H_9)_4$, triaryl- or trialkyltin hydroxides, or the analogous lead compounds. Typical uses include: diene polymerizations, ring opening polymerizations, alkylations, etc.

WC is used for reforming *n*-heptane, as a redox catalyst for the oxidation of hydrogen in fuel cells, and for the formation of hydrogen from water.

$W(CO)_6$ catalyzes a wide range of organic reactions, e.g., the metathesis of alkenes.

Sodium tungsten bronze catalyzes the oxidation of CO.

The sodium salt of 12-tungstophosphoric acid is used as a catalyst for isomerization, polymerization, nitrile synthesis, dehydrochlorination, dehydrogenation, ketone syntheses, and ring closure syntheses.

WS_2 and WSe_2 in the form of colloidal coatings have been tested for photocatalysis.

11. Economic Aspects [101]

The price of tungsten in ore concentrate depends on supply and demand, and is therefore subject to fluctuations (Fig. 12). It is expressed either as \$/STU (short ton unit = 20 lb WO_3 = 7.19 kg W) or in \$/MTU (metric ton unit=10 kg WO_3 = 7.93 kg W). In times of warlike confrontation, the strategic importance and consequently increased demand for tungsten have led to high prices. On average, prices increased until 1977, although this was partly caused by inflation. The price maximum reached in 1977 was a consequence of increased consumption. Hand in hand with this development, the mining of tungsten shifted from the developing countries to the highly industrialized countries. This was mainly to secure supplies in times of crisis. In 1970, 49 % of tungsten came from western industrialized countries. In 1980, this figure was 58 %, and 69 % was predicted for 1990. However, this figure was never reached, as the market share of the People's Republic of China had continuously increased (Fig. 13).

In 1977, world tungsten demand was still <40 000 t. As shown in Figure 13, demand continued to increase until 1989, reaching ca. 52 000 t, but the price fell from 1977 onward. Thus, the price control mechanism that had been operating well until then was obviously no longer effective.

Several circumstances were responsible for this:

Up to 1977, China, for long the most important exporter of tungsten ore concentrates, had been price conscious in its trading, as this was only carried out by state officials. Following the liberalization of trading in China, producers attempted to obtain foreign currency directly by quoting low prices. Internal competition and pressure from dealers led to continued price reductions.

This fall in prices was exacerbated by the fact that high-purity intermediate products, e.g., APT, blue tungsten oxide, tungstic acid, and ferrotungsten, were offered at the same price per unit of tungsten as ore concentrates. At the end of 1993, the price of high-purity APT was so low that even the Chinese producers were no longer able to sell at a profit.

The drastic fall in demand that started in 1990 and which was caused by the general recession, the breakdown of the communist world, and the associated decline in the armaments industry led to stabilization of the lower prices.

Quite simply, the low tungsten price and the fact that there was no price difference between ore concentrate and intermediate product led to the enforced closure of almost all the larger mines in North America, Europe, South Korea, and Australia, and the suspension of many associated industries based on the treatment of ore concentrates.

In consequence, not only has the proportion of tungsten supplied from the People's Republic of China increased (Fig. 13), but also the makeup of the products has changed (Fig. 14). Whereas China was still an exporter exclusively of tungsten ore concentrate in the early 1980s, today it is the largest supplier of high-purity tungsten intermediate products.

Thus, none of the predictions, e.g., 4 % annual growth, opening of new mines, further shifting of mine production to the industrialized countries, self-sufficiency, etc., has been fulfilled. World demand for tungsten has decreased drastically; China is the main supplier.

12. Tungsten Recycling

As stated in Chapter 3, large amounts of tungsten scrap have been used as a raw material for several decades. This is because of:

The value of the tungsten content
The value of other metals in the alloys, e.g., Ta and Co in hard metals and Ni in heavy metals
Environmental aspects
Economic aspects

Methods for the treatment of scrap and utilization of the recovered materials are optimized where possible in the light of these factors.

Both direct and indirect recycling processes are used. In direct recycling, scrap is converted from the compact form to a powder which is then recycled only to the process that produced the material from which the scrap originated. For this, the scrap must consist of one grade only, and must not contain heterogeneous impurities.

Figure 12. Average mid-range price of wolframite 1955 – 1992
From *Metal Bulletin*

Figure 13. Tungsten supply and demand 1985 – 1992

Figure 14. Tungsten supply in China 1981 – 1992

In the indirect process, scrap is chemically converted to materials from which the impurities and other components are removed, and is then converted to APT as described in Chapter 4.

The direct method is preferable for economic and environmental reasons, but it can be used only for certain types of scrap, and the demand for the recycled product is not always certain. For this reason, the proportion of scrap tungsten treated by conversion to APT is continually increasing.

Combined processes are also used, e.g., the selective separation and recovery of one alloying component. Examples include the leach milling of hard metal scrap to liberate the cobalt binder metal, leaving behind the carbide phase(s), which can be recycled to the hard metal production process.

A proportion of tungsten scrap goes to smelting metallurgy for the production of stellites, melting base alloys, menstruum WC, and steel.

The economics of various treatment processes for the important types of scrap are compared in Table 8.

13. Beneficial Effects on Human Health [102], [103]

In contrast to certain toxic effects of metallic tungsten and its compounds and alloys, some very beneficial effects on human health have been described. An aqueous solution of sodium tungstate (ca. 2 %) was taken orally, applied to the skin, used as a gargle or an eye lotion, or injected subcutaneously. Experiments on 100 people in Japan showed remarkably successful results with a wide range of illnesses, e.g., cataract, stomach ulcers, duodenal ulcers, cancer, diabetes, herpes, migraine, gout, cardiac arrhythmia, and many others. Tungstate is also beneficial in cases of mercury or selenium poisoning, burns, and sunburn, and it can counteract the unpleasant aftereffects of excessive alcohol consumption, as is also reported for molybdate. It has furthermore been established that the natural aging process is significantly retarded. It is to be hoped that funded scientific investigations into the action of tungstate will be undertaken as soon as possible.

Table 8. Tungsten recycling ∗ [13], [14]

Treatment of scrap	Hard metal scrap	Heavy metal		W – Cu	W – AG	Pure tungsten
		Hard	Soft			
Zinc process	B					
Coldstream	B		G			L
Bloating/crushing	B					
Oxidation/reduction			B			L
Hydrometallurgy		L	L	B	B	L
Electrolytic		L	L	B	G	L
Chlorination	L	L	L	L	L	L
Melting (ferrotungsten, stellite)	G	G	G			G

∗ B best economic use; G good economic use; L least economic use.

14. Toxicology and Occupational Health

Tungsten and most of its compounds generally show relatively low toxicity compared to most other heavy metals and their compounds. However, some tungsten compounds are more toxic than they were originally considered to be.

Intoxications with tungsten and its compounds are comparatively rare; they occur almost exclusively by occupational exposure.

Physiological responses, toxicokinetics, toxic effects, levels of tolerance, and ecotoxicity of tungsten and its compounds have been reviewed [104–106].

Toxicokinetics. In animal models, nearly one-half of ingested soluble tungsten compounds and roughly one-third of deposited inhaled tungsten trioxide aerosol is readily absorbed. Most of the absorbed tungsten is rapidly excreted in the urine. The remainder is distributed among the red blood cells, spleen, kidney, and bone. About 3 months after ingestion and 6 months after inhalation, most of the complete tungsten body burden has been transferred into bone. However, this amount is very small as compared to the administered dose [105]. The biological half-life of tungsten in bone is calculated at 1100 d for the slowest component of a three-component elimination kinetics [107].

Tungsten seems to have an influence on molybdenum homoeostasis. In rats, the addition of 100 ppm tungsten to a diet containing 30 ppm molybdenum caused a decrease in the activities of sulfite oxidase and xanthine oxidase, which led to a significant increase in the susceptibility of these animals to sulfur dioxide [108].

Acute Toxicity. Acute intoxications are caused especially by tungsten hexafluoride, WF_6. Liquid or gaseous WF_6 reacts readily with water, generating highly toxic hydrogen fluoride. Consequently, the mucous membranes of the respiratory tract and the eyes are damaged severely after contact with WF_6. Acute intoxication causes a strong irritation of the upper respiratory tract, laryngitis, and bronchitis; after a period of less severe symptoms the development of cyanosis and lung edema is possible [109].

In contrast, 25 – 80 g of powdered tungsten metal did not cause adverse effects when administered orally as a substitute for barium sulfate in radiological examinations [110].

Chronic Toxicity. Cemented tungsten carbide, WC, is suspected of causing respiratory diseases in humans. However, these effects are possibly not due to WC itself, but rather to its content of cobalt metal. In workers processing WC the development of interstitial pulmonary fibrosis has been reported [111], [112]; the clinical picture includes cough, exertional dyspnea, and weight loss. Abnormal gas transfer was detected in respiratory function tests.

In the case of a 33-year-old woman who was exposed to cemented WC for several years and who died after development of pneumoconiosis, an increased content of cobalt ions in bones and lung was demonstrated after autopsy [113]. In various test series with rats there were strong indications that cobalt was the main reason for the development of the lung diseases [114].

In long-term studies with rats and mice, 5 ppm tungsten (as sodium tungstate) was added to the drinking water during the life span of the test animals. In rats, growth development increased slightly, whereas the life span decreased significantly [115]. Mice did not show these effects [116].

Genotoxicity. In a long-term study with mice, in which 5 ppm tungsten (as sodium tungstate) was added to the drinking water during their life span, no tumorigenic effect was seen [116].

Reproductive Toxicity. In rats, tungsten causes an increased embryo lethality and decreased ossification of bones in a dose range with no toxic effects to the maternal organism [117]. Tungsten accumulates in the fetus without being retained significantly by the placenta.

In another study on the embryonic and fetal development in mice [118], tungsten was injected as sodium tungstate before implantation or at early organogenesis (on day 3 or 8 of pregnancy, injection of 0.1 mL of 25 mmol/L sodium tungstate). The treatment did not show any effect on implantation, but increased the frequency of resorption.

Immunotoxicity. In a patch test, no allergic reactions to Na_2WO_4 were seen on the skin of 853 hard-metal workers [119]. However, irritant pustular reactions appeared in 2 % of the test persons.

Toxicological Data. Tungsten: LD_{50} (rat, i.p.) 5000 mg/kg [120]; sodium tungstate, Na_2WO_4 (rat, s.c.) 223 – 255 mg/kg [121]; phosphotungstic acid, $H_3P(W_3O_{10})_4$: LD_{50} (rat, oral) 3300 mg/kg [122]; tungsten carbide, WC (containing 8 % cobalt): LDLo (rat, intratracheal) 75 mg/kg [123]; tungsten carbide, WC (containing 15 % cobalt): LDLo (rat, intratracheal) 50 mg/kg [123].

In humans normal mean blood levels are considered to be 5.8 (± 3.5) µg W/L [104].

Treatment. Dimercaprol (British Anti-Lewisite) may be useful in the treatment of acute tungsten poisoning [124]. Cortisone preparations have been proposed for decreasing the development of lung fibrosis [125].

Occupational Health. The MAK value is 1 mg/m^3 for tungsten and soluble tungsten compounds, and 5 mg/m^3 for tungsten carbide and other insoluble tungsten compounds, measured as total dust [126]. In the United States, NIOSH has set exposure limits (TLV-TWA) of 1 mg/m^3 for soluble and 5 mg/m^3 for insoluble tungsten compounds [127].

Lung fibrosis caused by tungsten or tungsten carbide is included in the list of the German Berufskrankheitenverordnung (Occupation Disease Regulations) [128].

Since tungsten tends to accumulate, persons exposed at the workplace should undergo periodical medical checks including chest X-rays and ventilatory function tests for insoluble tungsten compounds, as well as examinations of the digestive tract and the central nervous system for soluble tungsten compounds [129].

1. Turpentine as a Natural Product

Turpentine, which occurs in many natural forms, is a component of conifer balsam and plays an important role in the ecosystem of the pine forest [5]. It is part of the plant metabolism, and its individual components are important for the protective system of the conifers: for rapid closure of wounds to the bark by resin formation, for repelling insects (e.g., myrcene repels the pine beetle), and for protection against attack by bacteria (effect of, e.g., 3-carene).

The volatile terpenes (and polymers derived from them) emitted to the atmosphere are partially absorbed by the forest soil and contribute to humus formation [6]. This emission occurs to a great extent, particularly in summer. In Russian pine forests, terpene concentrations of 3.5 – 35 µg per cubic meter of air have been measured [7], [8]. In similar investigations in the state of Pennsylvania (total area 117 350 km^2, of which 62 000 km^2 is forest) an emission of 3400 t of terpene hydrocarbons was found for one day in the month of August [9]. The annual worldwide biogenic production of terpenes is estimated to be 10^9 t in 1984 [10]. Since this quantity is degraded by natural routes, the environmentally relevant terpenes can be considered problem-free with regard to air pollution. Only in combination with nitrogen oxides and with UV radiation may ozone be formed.

2. History

In ancient times turpentine obtained from conifer balsam was very important as a fuel for lamps and torches; as a solvent; as a fragrance; and as an embalming oil. Cuneiform script texts and archaeological finds indicate that turpentine was known by around 3000 BC in Mesopotamia [11] and Pakistan [12]. The preparation and use of distilled cedarwood oil ("turpentine oil" from *Pistacia terebinthus*) were described in early Egyptian culture (e.g., for embalming [13]). Turpentine was also known to the Greeks, Celts, and Romans. In alchemists' books of the 13th century, turpentine oil was described as *aqua ardens*, and in the distillery book of the Strasbourg doctor H. Brunschwygh (1450 – 1543) as *spiritus terpenthinae*.

In China, turpentine was used early on as a solvent for rosin (colophony) for impregnating

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_267

sail canvas and rigging and sealing ships' hulls. This kind of use was very important among the maritime powers in the Middle Ages.

In Europe, *gum spirit of turpentine* (also known as *gum turpentine*) was produced in the 16th century in Poland, Germany, Scandinavia, and Russia; in the 19th century in France, Spain, Portugal, and Finland; and since 1902 in Greece. In North America, turpentine has presumably been extracted since 1606 in Nova Scotia. Since 1710 it has been produced to a greater extent in North Carolina, and later in other states. For a long time a mixture of turpentine and spirit – the lamp fuel camphine – was an important commercial product.

In ca. 1870, steam distillation of turpentine was introduced, followed in 1910 by extraction from tree stumps left after deforestation. In this way, the cheaper *wood turpentine* and *pine oil* came on the market.

Sulfate turpentine, a byproduct of pulp production, was obtained in small quantities in Norway and Sweden already before 1910, in Finland since 1911, and in the United States since 1918. Only since 1930 has it been available in large quantities as a low-priced raw material [14]. From 1954 onward its production in the United States overtook that of all turpentines of other origins.

The first elemental analysis of turpentine was carried out in 1818 by J. J. Houton de Labillardiere. A little later the essential oils of gum turpentine were investigated scientifically by J. B. Dumas (1833), J. J. Berzelius, J. von Liebig, and F. Wöhler (1837). In 1862, M. Berthelot began his studies on terpene hydrocarbons (e.g., pinene hydrochloride), and 1877 W. Tilden began to characterize the hydrocarbon components of spirit of turpentine by means of their crystalline nitrosyl chlorides. In 1884, O. Wallach succeeded in structurally characterizing the components of turpentine oils, and in 1893 A. von Baeyer began exploring the field of cyclic terpenes [15]. More recently, the biosynthesis of monoterpenes has been investigated by many scientists [16–21].

3. Definition and Classification

Turpentine [*8006-64-2*] (oil of turpentine, turpentine oil, spirit of turpentine) is the collective name for the volatile components of the crude resins (balsam or oleoresin, Latin: *resina terebinthi*) from conifers, particularly the pine family. The turpentines represent a subgroup of plant and tree saps (essential oils).

Depending on the starting material and production method, the following types of turpentine are defined according to DIN 53 248 (April 1977): gum spirit of turpentine, steam-distilled wood turpentine, refined sulfate wood turpentine, and destructively distilled wood turpentine.

The use of the term turpentine without further specification is not permitted. Usually, the name of the country of origin is added (e.g., Greek gum spirit of turpentine). The addition of products that are not typial components of turpentine must be declared.

Gum spirit of turpentine (Latin: *oleum terebinthinae*, French: *essence de térébinthine*, German: *Balsamterpentinöl*) according to DIN 53 248 denotes only the pure essential plant oil obtained by distillation of the resin exudate (balsam or turpentine) from living trees of the genus *Pinus* at up to 180 °C (under normal pressure). The name must not be used for material obtained after the extraction of several components (e.g., pinene).

Steam-distilled wood turpentine (French: *essence de bois distillée à la vapeur*, German: *Wasserdampfdestilliertes Wurzelterpentinöl*) is a turpentine obtained either directly from the steam distillation of finely chopped wood from roots and stumps of trees of the *Pinus* family or after extraction with solvents, which is otherwise unchanged.

Refined sulfate wood turpentine (French: *essence de bois dite au sulfate* or *essence de papeterie de sulfaté desodorisée*, German: *Gereinigtes Sulfatterpentinöl*) is a byproduct of pulp production using the soda or sulfate pulping process (→ Paper and Pulp, Chap. 1.3.2.), that is subsequently purified.

Crude sulfate turpentine (French: *essence de papeterie de sulfate brute*, German: *Rohsulfatterpentinöl*), which is not purified, is now rarely marketed, because the sulfur compounds it contains produced a nauseating odor.

Destructively distilled wood turpentine (French: *essence de bois par destillation destructive*, German: *Gereinigtes Kienöl*) is the name given to the oil obtained by dry distillation of resin-rich pinewood followed by purification. It must not be called turpentine or oil of turpentine.

Sulfite turpentine and pine oil are not defined according to DIN 53 248, but are generally related to the other turpentines (see Section 4.4, Chap. 16). Sulfite turpentine is a byproduct of pulp production by the sulfite pulping process (→ Paper and Pulp, Chap. 1.3.2.). Its composition (main component *p*-cymene) differs significantly from that of the other turpentines [22].

The term *naval stores* relates to all rosin and oil products extracted from conifer wood, such as turpentine, rosin (→ Resins, Natural, Chap. 5.), pine oil, or tall oil (→ Tall Oil). It originates from the time when the United States was still an English colony and when these types of product were used widely in shipbuilding (e.g., in paint, to seal ships' hulls, or to treat rigging) and were therefore stored and sold in naval stores (→ Resins, Natural, Chap. 5.).

4. Production

4.1. Gum Turpentine

Gum turpentine is extracted in many countries with warm climates (more frequently in the Northern Hemisphere) from the wood resin or crude balsam of various conifers, particularly those of the pine family (see also → Resins, Natural, Chap. 5.1.) [23]. Incisions made in the trunks of fully grown trees are deep enough to allow crude balsam to flow out of the resin channels. It can then be collected in removable vessels. These mostly V-shaped cuts ("lachte") may be applied only to a small section of the circumference to protect the tree and must be extended upward or downward several times a month. A further development involves inserting poly(ethylene terephthalate) bottles or small polyethylene bags into holes that have been bored in the bark and injected with an irritant. In this way, not only is the tree protected, but oxidation and contamination of the balsam and evaporation of the terpenes are avoided [24].

The crude balsam collected is first freed of foreign material, such as sand, wood, etc. To this end, either in molten form or dissolved in turpentine, the balsam is filtered through a finely meshed sieve. To remove irritants, etc., the product is washed with hot water and distilled. Normal distillation has been replaced extensively by more gentle steam distillation [3]. Rosin remains as the turpentine-free residue. It is removed as the molten resin and transferred to metal drums.

In certain operations, solid high-boilers (pitch) can also be formed. These compounds are found in wood extracts in quantities of 2 to 8 % and consist mainly of triglycerides, fatty acids, resin acids, and waxes [25].

The annual yield of crude balsam per tree is ca. 1.5 kg for Scots pine, 2.5 – 4 kg for black pine, and ca. 0.6 kg for spruce. With Central American species, more than 5 kg can be obtained. The average proportion of turpentine is 13 – 25 %.

By means of resinification using irritants – i.e., treating cuts in the tree with mineral acid, particularly sulfuric acid; with the herbicides diquat and paraquat; or with 2-chloroethylphosphonic acid (CEPA) – the yield can be increased two- to fivefold [24], [26], [27].

4.2. Wood Turpentine

Wood turpentine is now produced in only a few places, such as the United States (see also → Resins, Natural, Chap. 5.2.). It is extracted from finely chopped stump wood either by steam distillation or with solvents such as naphtha or chlorohydrocarbons (under pressure if required). The extract is subjected to either fractional or steam distillation. Wood turpentine is obtained as the lower-boiling fraction and pine oil as the higher-boiling one. Limonene can sometimes be isolated as an intermediate fraction [28], [3]. Ca. 2.2 wt % turpentine, 1.5 wt % pine oil, and 0.4 wt % limonene can be extracted from stumps of yellow pine that are at least eight years old. From stumps of Scots pine, only ca. 0.75 wt % turpentine is obtained. The yield increase with the age of the stump because the hollows between the dead and dried-out cells fill with turpentine balsam. This enrichment can be accelerated by boring holes in the tree just above

the roots two years before felling and filling the holes with paraquat [29].

4.3. Sulfate Turpentine

Sulfate turpentine is isolated as a byproduct in pulp production (→ Paper and Pulp, Chap. 1.5.1.) and is most important in the United States, Scandinavia, and Russia.

In the kraft (sulfate) pulping process, debarked and finely chipped wood is heated to 150 – 180 °C in an aqueous digestion liquor containing NaOH, Na_2S, Na_2CO_3, and small quantities of Na_2SO_4, Na_2SO_3, and $Na_2S_2O_3$ in large pressure vessels at 7 – 13 bar for 1 – 5 h. Crude sulfate turpentine is condensed from the waste gas from the digester and is separated from the water (→ Paper and Pulp, Chap. 1.3.1.1.). The process can also be carried out continuously in horizontal or vertical tube digesters [30–34] (→ Paper and Pulp, Chap. 1.4.1.), enabling more than 74 % of the turpentine originally present to be extracted.

Crude sulfate turpentine still contains 5 – 15 wt % sulfur compounds with very nauseating odors, mainly methanethiol, dimethyl sulfide, and dimethyl disulfide [35]. These can be oxidized with sodium hypochlorite solution (bleaching liquor) at ca. 60 °C to the less volatile sulfonic acids, sulfoxides, or sulfones [36], which can be removed by washing with water or by distillation. Additional methods for removing sulfur compounds are treatment with chloride of lime [37] or sodium peroxide [38], careful distillation [39], and blowing air or inert gas through the product. These measures may be used individually or in combination. Even extensively purified sulfate turpentine contains traces of sulfur and chlorine compounds, which give a characteristic musty odor.

The yield of sulfate turpentine is 6 – 16 kg per tonne of pulp for pine, ca. 2 kg per tonne for spruce, and 2 – 3 kg per tonne for fir trees. The location and date of the wood harvest and the length of the storage period before processing affect the yield. In winter, up to 30 % more turpentine can be obtained than in summer. Wood chips can lose up to 80 % of their turpentine content in ten weeks [40].

About 55 % of the pulp factories worldwide use the sulfate digestion process.

4.4. Sulfite Turpentine

Sulfite turpentine is a byproduct of pulp production by the sulfite process (→ Paper and Pulp, Chap. 1.3.2.). Very small wood chips are heated in pressure vessels (pulp digesters) with pulping liquor. The latter consists mainly of $Ca(HSO_3)_2$ and SO_2 in acid bisulfite pulping (pH 1.5 – 2); $Mg(HSO_3)_2$ in bisulfite pulping (pH 4); and Na_2SO_3, $NaHCO_3$, $(NH_4)_2SO_3$, and NH_3 in the neutral sulfite process (pH 7 – 9). Wood chips are first impregnated at temperatures that increase to 110 °C under alternating reduced and overpressure. Then they are digested at 125 – 160 °C and 7 – 13 bar. The overall process takes 6 – 10 h [34], [41–44]. After the waste gas has been driven off, the crude oil separates on top of the pulping liquor as a yellow-brown, weakly green-fluorescing liquid. From this the almost colorless sulfite turpentine, *bp* 176 –180 °C, is obtained by neutralization with sodium hydroxide or lime and distillation (possibly using steam) in a yield of 0.3 – 1 kg per tonne of pulp [37]. Sulfite turpentine consists of 70 – 90 % *p*-cymene, which is formed from the terpene components originally present in a reaction catalyzed by hydrogensulfite. It also contains dipentene, borneol, and other mono- and sesquiterpenes [22] and, when mild digestion conditions are used, significant quantities of α-pinene.

4.5. Destructively Distilled Wood Turpentine

The production of destructively distilled wood turpentine by the dry distillation of resin-rich pinewood (predominantly stumps) is no longer important. For more information, see [45]. This product contains little α-pinene, but high quantities of limonene (dipentene), *p*-cymene, camphene, α-terpinene, and sylvestrene.

5. Composition

The main components of turpentines are mono- and bicyclic monoterpenes ($C_{10}H_{16}$; M_r 136.2). They also contain smaller quantities of terpene – oxygen compounds (e.g., terpene alcohols), sesquiterpenes ($C_{15}H_{24}$), and other compounds (see Fig. 1).

Figure 1. Turpentine constituents and downstream products

The composition of different turpentines depends on the species of pine from which they are extracted [46]. About 105 species and varieties have now been described which can be distinguished to only a limited extent on the basis of turpentine composition (their "terpene pattern"). Species of pine that are important for turpentine extraction are listed in Table 1.

Table 1. Species of pine that are important for turpentine extraction

Habitat	Systematic name	Common name
Western Europe	*P. pinaster* Sol.	French maritime pine
Southeastern Europe	*P. nigra* Arnold	black pine, Austrian pine
Greece	*P. halepensis* Mill.	Aleppo pine
Mid- and Eastern Europe and Russia	*P. sylvestris* L.	Scots pine
Siberia	*P. pumila*	
China	*P. massoniana*	Chinese red pine
	P. langbianensis	
	P. elliottii Engelm.	slash pine
India	*P. longifolia* Roxb.	
Southeast Asia	*P. armandi*	
Indonesia	*P. mercussii* Junk	Mindoro pine
United States	*P. palustris* Mill.	longleaf pine
	P. ponderosa Laws	yellow pine
Southwest USA	*P. edulis* Engelm.	
Southeast USA	*P. taeda* L.	loblolly pine
	P. elliottii Engelm.	slash pine
South Brazil	*P. elliottii* Engelm.	slash pine
	P. taeda	loblolly pine
Argentina	*P. taeda* L.	loblolly pine
	P. elliottii Engelm.	slash pine
Mexico	*P. oocarpa* Schiede	
Honduras	*P. montezuma* and others	
Northern Brazil	*P. caribaea* M.	
Venezuela	*P. caribaea* M.	

The habitat of the trees generally has little effect on the ratio of components in the turpentine oil extracted. However, for some varieties of pine (e.g., *Pinus ponderosa* Laws) the turpentine varies significantly depending on the climate, age, and habitat of the trees [47], [48].

α-Pinene is the main component of most turpentine oils. Many turpentines also contain large quantities of β-pinene, *d*- or *l*-limonene (or its racemate dipentene), 3-carene, or α-terpinene (sometimes up to 15 %). Table 2 gives a simplified overview of the average composition and physical properties of various turpentines. The turpentine oils on the market are not specified according to species of pine but according to producer country, so that rather pronounced deviations in composition are possible, depending on starting material. More details can be found in [1–3], [49], [50] (with many additional references).

Besides the components listed in Table 2, turpentines can also contain α- and γ-terpinene, α- and β-phellandrene, terpinolene, myrcene, *p*-cymene, bornyl acetate, anethole, sesquiterpenes (such as longifolene; up to 20 % in *Pinus longifolia* Roxb.), heptane, nonane, and many other compounds [51]. Some turpentines do not contain α-pinene as the main constituent but, for example, β-pinene (75 % in *Pinus clausa* Engelm.), *l*-limonene (80 % in *Pinus pinceana* Gordon), β-phellandrene (96 % in *Pinus contorta* Douglas), or heptane (95 % in *Pinus sabiniana* Douglas).

Turpentines usually contain 0.3 – 2.5 wt % of nonvolatile components in the evaporation residue, or considerably more if resinification occurs due to improper storage or handling.

Turpentines from spruce or fir contain significantly less α-pinene but higher quantities of camphene, α-terpinene, phellandrene, myrcene, cyclofenchene, and bornyl acetate, for example.

6. Physical Properties

Turpentines are colorless to pale-yellow liquids with low viscosity and a characteristic odor. In gum turpentine this odor is pleasantly aromatic. The physical data can vary within certain limits, depending on composition (see Table 2):

Boiling range (101.3 kPa)	150 – 177 °C
Solidification point	<-40 °C
ϱ (20 °C)	0.855 – 0.872 g/mL
$[\alpha]_D^{20}$	-40 to $+48°$
n_D^{20}	1.465 – 1.478
Relative evaporation rate (diethyl ether: 1)	ca. 170
Calorific value	ca. 40 000 kJ/kg

Turpentines are miscible with most organic solvents, but immiscible with water. They are also good solvents for hydrocarbon resins, waxes, paints and coatings, fats, and oils. Ca. 0.06 wt % of water is absorbed at 20 °C.

Turpentine is not listed in either DAB 10 or the European Pharmacopoeia.

Table 2. Simplified overview of the composition of turpentines of different origins

Type, origin	Proportion in wt % of					Density at	Rotation, $[\alpha]_D^{20}$	Distillation range at
	α-Pinene	β-Pinene	Camphene	3-Carene	Limonene (dipentene)	20 °C, g/mL		101.3 kPa, °C

7. Chemical Properties

The chemical properties of turpentine are determined by its major components, particularly the reactive pinenes. Typical reactions include isomerization, disproportionation, and polymerization catalyzed by acids, acid salts, surfactants, or Friedel – Crafts catalysts. Hydrates can be formed in the presence of water. Addition reactions take place with halogens, hydrogen halides, and nitrosyl chloride. Turpentine reacts with phosphorus pentasulfide and hydrogen sulfide to form complex sulfur compounds and thiols. Carboxylic acids add to give esters, and alcohols to give ethers. Pyrolysis yields mixtures of acyclic and monocyclic terpenes, pyronenes, hydroterpenes, and *p*-cymene. Moist air leads to autoxidation of α-pinene to sobrerol (*trans-p*-menth-6-ene-2,8-diol) and resins. These reactions can be inhibited by the addition of 0.005 – 1.0 % of certain amines or phenols acting as antioxidants (e.g., diphenylamine, thymol, catechol, resorcinol, pyrogallol, naphthols, or 2,6-di-*tert*-butyl-*p*-cresol) [52], [53].

8. Analysis

German Standards. The usual tests that should be referred to in test reports are listed in DIN 53 248 (solvents for paints, turpentine, and destructively distilled wood turpentine, April 1977). Besides appearance, color, and odor, the following characteristics should be determined:

Density	(DIN 51 757, ISO 279)
Refractive index	(DIN 53 169, ISO 280)
Flash point	(DIN 53 213; ISO 3679)
Acid number	(DIN 53 402, ISO 709)
Distillation range	(DIN 53 171 with limitations according to DIN 53 248, ISO 3405)
Residue on evaporation and material insoluble in sulfuric acid	(DIN 53 248, ISO 4715)

Determination of the residue on evaporation should be carried out under a weak stream of nitrogen to avoid oxidation and, thus, erroneous results. Determination of the bromine number of turpentines has not been standardized internationally [54].

U.S. Standards. In the United States, specifications according to ASTM D 13-92 for appearance, color, odor, and physical data of various turpentines are used. Sampling and testing must be carried out according to ASTM D 233-92. The sulfur present in sulfate turpentine, mostly in the form of volatile compounds, can be determined according to ASTM D 1266-91 [55].

Steam-distilled wood turpentine always contains traces of benzaldehyde. Detection of the latter is characteristic of this turpentine [56].

Methods of Analysis. Gas chromatography is used most frequently for the determination of individual components (DIN 51 405, ASTM E 260-91) [57–60]. Capillary columns with surface coatings [e.g., 50-m steel capillary columns with poly(propylene glycol) or poly(phenyl ether) coating or 25- or 50-m glass capillary columns with Carbowax 20 M or dimethylsilicone coating] are particularly effective. Accurate evaluation of gas chromatograms is occasionally difficult because of the possibility of complex reactions, such as isomerization or dehydration, in the injection unit or the column [61].

Head space gas chromatography (HSGC) has proved useful for the investigation of natural products [62].

9. Safety and Occupational Health

Turpentines are volatile, flammable liquids whose vapors are 4.7 times heavier than air; they can form explosive vapor – air mixtures on being heated above the flash point.

Flash point	32 – 35 °C
Ignition temperature	220 – 240 °C
Explosion limits (101.3 kPa)	ca. 0.8 – 6 vol % (45 – 340 g per cubic meter of air)
Ignition group (according to VDE 0165)	G 3

Handling of turpentine above the flash point must be carried out in explosion-proof apparatus [63]. Furthermore, the fact that turpentine can self-ignite in contact with air on distribution over large surface areas (e.g., on cleaning cloths or insulating materials) must be taken into account. Turpentine also ignites on contact with concentrated nitric acid.

MAK value	100 ppm (560 mg/m^3) [64]
Short-term exposure limit	5 min 2 × MAK 8 times per day
Sensitization	hypersensitive reactions of skin and respiratory tract are possible
Skin absorption	poisoning through skin absorption is possible

When handling turpentine, inhalation of the vapor, swallowing, and contact with the skin or eyes should be avoided (see Chap. 14). According to GefStoffV the following container labeling for turpentine is stipulated: St. Andrew's Cross and symbol for flammable liquids. In Germany further security information is given in VBG 1 (UVV 1 of BG Chemie), Kühn-Birett Merkblatt T 02, and Hommel-Merkblatt 190.

Both "spirit of turpentine" [*8006-64-2*], EINECS no. 232-350-7 and "turpentine, its extracts and physically modified derivatives" [*9005-90-7*], EINECS no. 232-688-5 are listed in the register of existing substances (EINECS) according to ChemG (September 1981).

10. Storage and Transportation

Turpentines should be stored in locations that are as cool as possible. Light, air, and acidic substances should be excluded to minimize changes in composition. The regulations governing equipment for storage, filling, and transport of substances hazardous to water and the regulations governing flammable liquids (VbF) must be adhered to.

The following classifications are used for the storage and transportation of turpentine:

VbF	group A class II
GGVE/GGVS	class 3, item 31 c
RID/ADR/ADNR	class 3, item 31 c
IATA/DGR	2319
IMDG code	class 3.3 – 2319
UN no.	2319

According to the GGVS for road transportation of turpentine, labeling with orange hazard notices and the labeling no. 30/2319 is stipulated. The same applies to α-pinene (labeling no. 30/2368).

11. Ecological Aspects

Being truly natural products, turpentines and their individual components are completely biodegradable usually in a few days, depending on the degree of dilution, temperature, availability of air, and presence of bacteria. Nevertheless, according to current estimation of the potential

hazard to water, and in view of the great variety of turpentines they are assigned to the German water hazard class II (WGK II). Below their solubility limit, they do not represent any hazard to biological wastewater-treatment plants.

Turpentines are not classified in TA Luft, but by analogy to pinenes, they may be assigned to TA Luft hazard class III.

The ozone depletion potential (ODP) and the global warming potential (GWP) of turpentines are given as zero. Even the Clean Air Act of 1990 does not list terpenes among the 190 substances that cause air pollution [65].

12. Uses

The direct use of turpentine is now limited mainly to that as a solvent or dilution agent, e.g., for natural or modified binders (mainly alkyd resins), for oils, coatings, resins, paints (also artists' paints), and floor and shoe polishes (→ Solvents, Chap. 9.3.). It accelerates, for example, the drying of coatings and paints by peroxide formation, in particular of those based on drying oils or other film-forming agents. Higher-boiling turpentine fractions (containing large quantities of 3-carene) are suitable as pesticides for use in forestry [66].

Although the importance of unfractionated turpentine as a solvent has clearly decreased as a result of the use of cheaper petrochemical products, turpentine has attracted increasing interest as a raw material for the chemical industry. By fractionating distillation under reduced pressure, it can be separated into fractions or individual components. Separation by process-scale chromatography has also been described [67]. The main product is usually α-pinene, whose purity can reach 99 %. β-Pinene [68], 3-carene, and monocyclic terpenes [α-terpinene, limonene (dipentene), and phellandrene] are obtained in smaller quantities. Higher-boiling fractions are obtained from the residue by steam distillation. Terpene alcohols, sesquiterpenes, and diterpenes are thus obtained. The resin remaining has a composition similar to rosin and can be used for the same applications.

From the residue of sulfate turpentine distillation, estragole [*140-67-0*] (1-allyl-4-methoxybenzene) and anethole (1-propenyl-4-methoxybenzene), mostly contaminated with caryophyllene, can also be obtained.

From the different components of turpentine, particularly α- and β-pinene, a large number of substances are synthesized, some on an industrial scale. This is shown in simplified form in Figure 1 (see also [69–74] with many additional references).

The following possible uses of turpentine and its downstream products are known (→ Terpenes, Chap. 1.5.):

1) Flavors and fragdances Flavors and Fagrances, Chap. 2.2., Flavors and Fagrances, Chap. 2.3.)
2) Pharmaceuticals (e.g., camphor, menthol)
3) Disinfectants (e.g., terpineol, *p*-cymene)
4) Pesticides (e.g., toxaphene, 3-carene, terpene halides and thiocyanates)
5) Cleaning agents (e.g., dipentene, *d*- or *l*-limonene)
6) Solvents (e.g., turpentine and its individual components *p*-cymene, *p*-menthane, and pine oil)
7) Resins (e.g., β-pinene polymers)
8) Varnish resins (e.g., terpene phenols, isobornyl acrylate, and terpene – maleate resins)
9) Melt adhesives (e.g., terpene polymers, terpene phenols)
10) Polymerization accelerators for rubber (e.g., pinane or *p*-menthane hydroperoxide)
11) Antioxidants (e.g., isobornyl phenols)
12) Plasticizers (e.g., camphor, esters of pinic acid)
13) Lubricating oil additives (e.g., sulfur-containing terpenes)
14) Traction fluids (e.g., terpene ethers)
15) Textile auxiliaries (e.g., terpineol, pine oil)
16) Flotation aids (e.g., pine oil)

In case of overproduction sulfate turpentine may occasionally be used as a fuel (e.g., in Canada).

13. Economic Aspects

The worldwide production of turpentines in 1990 was ca. 315 000 t, of which ca. 190 000 t was sulfate turpentine. A breakdown of production among the most important producer coun-

Table 3. Turpentine production (1000 t/a) in the most important producer countries with percentage of sulfate turpentine; 1990

Country	1960	1970	1980	1990	Sulfate turpentine, %
United States	99	94	86	105	97
Russia	28	42	30	54	85
China	10	30	65	48	2
Portugal	15	20	22	13	5
Finland		11	12	12	100
Sweden	2	9	9	10	100
Brazil				10	
Argentina			1	7	30
Mexico	9	8	11	6	10
Indonesia				6	0
New Zealand				4	0
India	5	7	8	4	0
Spain	12	9	5	2	90

tries is shown in Table 3 [75], with the proportion of sulfate turpentine given in each case [73]. According to this table the most important producer is still the United States. Although turpentine production has stagnated or decreased in many countries, its importance has increased markedly since ca. 1980 in the People's Republic of China and South America, where significant afforestation is being carried out. In these countries, predominantly gum turpentine is produced, whereas gum and wood turpentine production has become insignificant in the United States [75] (Table 4), the former because of the high extraction costs and the latter because of the dwindling supply of tree stumps.

The price of turpentine (and downstream products) is subject to considerable variation, as can be seen for *American sulfate turpentine* between 1977 and 1993 (midyear prices in dollars per gallon, prices in DM per 100 kilogram in parentheses).

1977	0.51	(31.20)
1979	0.72	(40.30)
1980	1.16	(64.30)
1981	1.74	(120.00)
1982	0.95	(70.40)
1983	0.69	(53.80)
1984	0.64	(55.60)
1985	0.75	(67.30)
1986	0.97	(64.20)
1987	0.83	(45.50)
1988	1.09	(58.50)
1989	2.10	(120.50)
1990	1.90	(93.70)
1991	1.49	(75.50)
1992	1.10	(52.30)
1993	0.70	(35.30)

The price of *gum turpentine* can differ according to origin and quality. It is also subject to large variations that do not, however, inevitably parallel those of sulfate turpentine. The average prices for Chinese gum turpentine (cost insurance freight, cif) may be cited as an example (source: Stat. Bundesamt Wiesbaden):

1989	$ 70.30 per 100 kg
1990	$ 68.40 per 100 kg
1991	$ 76.60 per 100 kg
1992	$ 68.00 per 100 kg
1993	$ 75.90 per 100 kg

Turpentines and their downstream products are expected to be very important in the future since they represent a continually renewable source of raw materials. Their yields can be increased considerably by cultivation of pine species that are richer in turpentine and less susceptible to pests or unfavorable weather conditions; by extending the area under cultivation; and by intensification of resinification using irritants.

14. Toxicology

Oil of turpentine (in vapor form also) causes characteristic and pronounced irritation of the skin and of the mucous membranes of the respiratory organs and eyes. It also leads to sensitization [76]. The LD_{50} values of 1.4 – 5.2 g/kg for rat [77] and the human lethal dose of 60 – 100 g per person [78], which was derived from cases of poisoning, show that the acute oral toxicity is relatively low. In the rat, the *acute inhala-*

Table 4. Proportions of different types of turpentine (given in %) in the United States

Type of turpentine	1950	1960	1970	1980	1990
Gum turpentine	38.4	19.7	4.5	1.0	0.1
Wood turpentine	33.5	26.9	16.4	8.0	2.9
Sulfate turpentine	27.4	53.4	79.1	91.0	97.0
Destructively distilled wood turpentine	0.7				

tion toxicity (LC_{50}) after 1 – 6 h of exposure is 12 – 20 mg/L [77].

Apart from biological scattering, variations can be explained by the varying compositions of different types of turpentines. The LD_{50} values (oral, rat) or turpentine are in the same range as those of its main components [79], [80]:

α-Pinene	2.1 – 3.7 g/kg
β-Pinene	4.7 – 5 g/kg
Camphene, *d*- and *l*-limonene	>5 g/kg
3-Carene	4.8 g/kg

The potential *skin irritation and sensitization* is greater in the case of old resinified turpentine because of the oxidation products formed. Of the main components, 3-carene clearly causes sensitization in humans and animals. Camphene and *l*-limonene do not have a sensitizing effect in humans, and α-pinene shows this effect only after oxidation – it has little or no effect as a purified product. The results for β-pinene and *d*-limonene are contradictory. Here, too, purity plays a part in the sensitizing potency [80]. The irritating effect on the mucous membranes of humans is pronounced: liquid turpentine and its vapors irritate the eyes and the respiratory tract at concentrations of >100 ppm (560 mg/m^3).

The *oral intake* of turpentine can cause irritation of the stomach, intestines, and urogenital tract, as well as vomiting, spasms, nausea, and kidney lesions.

Turpentine oil is easily absorbed through the skin. Although this route of application can cause damage, turpentine was used in the past in human and veterinary medicine to improve blood circulation in the skin.

In industry, however, uptake of turpentine is taken in primarily via the respiratory organs. Inhalation of higher concentrations (>100 ppm) causes not only irritation of the respiratory organs, but also headache, dizziness, increased pulse rate, and in rare cases, reversible impairment of kidney functions. Hardly any information exists on the chronic damaging effects caused by inhalation of low concentrations. Part of the turpentine absorbed parenterally is excreted unchanged by respiration. The largest part is oxidatively metabolized and excreted in urine as glucuronide [81].

The odor of turpentine is perceptible at concentrations as low as ca. 200 ppm (1.12 g/m^3). Since even this concentration causes irritation of the eyes and respiratory tract, it acts as a warning signal.

In the case of the inadvertent ingestion of turpentine, vomiting must be prevented and a doctor called immediately.

15. Turpentine Substitute

Turpentine substitute is frequently used instead of turpentine, mainly for economic reasons. The name is a collective term for colorless, flammable liquids that are similar to turpentine in their volatility and solubilizing capacity for resins, coatings, waxes, etc. The term includes high-boiling naphthas (140 – 170 °C), particularly those with high aromatics contents, as well as hydrogenated hydrocarbons, decalin, and tetralin. Essential oils can be added to improve the odor. *Hydroterpine* (hydrogenated destructively distilled pine oil) and distillation and rearrangement products of turpentine, consisting mainly of monocyclic monoterpenes, are more closely related to turpentine.

Trade names include Depanol I, Dipentene, Solvenol, Terposol, Unitene, and Yarmor [82].

The orange-peel terpenes may also be considered to belong to this group. They consist mainly of *d*-limonene. Those produced industrially are being used increasingly as cleaning agents, e.g., for printed circuit boards in microelectronics (as a replacement for chlorofluorocarbons).

16. Pine Oil

16.1. Production

Originally the name pine oil was given only to the higher-boiling distillation fractions (boiling range >180 °C) obtained in the production of wood turpentine (steam-distilled pine oil, see Section 4.5) or of American pine oil (destructively distilled pine oil) [2], [83].

As a result of the decrease in production of these natural pine oils and the simultaneous increase in demand, *synthetic pine oils* have become more important. They currently account for more than 90 % of sales. Synthetic pine oils are mostly produced by hydration of α-pinene or pinene-rich turpentine fractions by use of dilute mineral acids, usually sulfuric acid, at elevated temperature [84]. After separation of the aqueous phase, they can be purified by vacuum or steam distillation. Higher-grade products are obtained by carrying out the hydration at moderate temperature to give the solid terpin hydrate. The latter is dehydrated in a weakly acidic medium, after separation of the liquid phase, and then distilled.

16.2. Properties

Pine oils are flammable, colorless to yellow, oily liquids with pleasant odors. Their main components are terpene alcohols, particularly α-terpineol.

Natural pine oils can contain the following:

50 – 70 %	α-terpineol
5 – 10 %	borneol (and isoborneol)
5 – 10 %	fenchol
5 – 15 %	other terpene alcohols (e.g., *p*-menthan-8-ol, β-terpineol, terpin)
0 – 10 %	terpinyl and bornyl acetate
0 – 3 %	monoterpenes (e.g., pinenes, dipentene, terpinolene)
5 – 10 %	other components (e.g., cineols, camphor, anethole, estragole, sesquiterpenes)

Synthetic pine oils generally do not contain borneol, camphor, esters, anethole, and sesquiterpenes. The proportions of the components can vary within wide limits:

50 – 95 %	α- and γ-terpineol
3 – 20 %	other terpene alcohols (e.g., β-terpineol, terpinen-1-ol, and fenchol)
0 – 30 %	terpenes (e.g., 3-carene, terpinene, dipentene, and terpinolene)
1 – 10 %	1,4- and 1,8-cineol

Pine oils are characterized according to their terpene alcohol content (e.g., pine oil 70). The terpene alcohol content is normally ca. 60 – 80 % but can be 20 – 95 % after appropriate fractionation.

Pine oils are insoluble in water, but can be emulsified by use of dispersion agents such as soaps. Their *physical properties* lie mostly within the following limits:

ϱ (20 °C)	0.90 – 0.94 g/mL
n_D^{20}	1.475 – 1.488
Distillation range (101.3 kPa)	180 – 225 °C
Flash point	45 – 90 °C

The *chemical properties* of pine oils are determined mainly by the α-terpineol content.

16.3. Storage and Transportation

Pine oils should be stored in closed containers with the exclusion of heat sources. The relevant regulations governing equipment for storage, filling, and transportation of substances hazardous to water and regulations governing flammable liquids (VbF) must be adhered to. The classifications listed in Table 5 are in use, depending on the flash point.

Table 5. Regulations governing storage and transportation of pine oils

Regulation	Flash point	
	Below 55 °C	Above 55 °C
VbF	group A, class II	group A, class III
GGVE/GGVS	class 3, item 31c	class 3, item 32c
RID/ADR/ADNR	class 3, item 31c	class 3, item 32c
IATA – DGR	1987, at flash point >60.5 °C	
	no limitations	
IMDG-Code	class 3.3 – 1987	class 3.4 – 1987
UN-No.	1987	1987
Transport labeling according to regulations governing hazardous substances	30/1987	1987

Pine oil is not cited in the register of existing substanes (EINECS) according to the

ChemG. However, the CAS registry no. and the EINECS no. of its main component terpineol [*8000-41-7*], EINECS no. 232-268-1, may be assigned to it.

16.4. Uses

Pine oils are used mainly as foaming agents in the flotation of copper, lead, and zinc ores [85], [86] and sylvinite [87]. They have also been employed for the separation of poly(vinyl chloride) from mixtures of plastics [88]. Pine oils are good solvents for many paints and can be used as deodorants and disinfectants, as antifoams, and as additives for insecticides and wood preservatives [89]. Furthermore, they are used for the production of lubricants, emulsions, shoe and floor polishes, metal cleaners, and textile auxiliaries [90].

In the chemical industry, pine oil is used for the isolation of α-terpineol, which crystallizes from pine oil on cooling to less than ca. $-2\,^{\circ}C$ (depending on concentration) or is obtained from pine oil distillation.

16.5. Economic Aspects

Besides a few South American and European (French and Austrian) pine oil-producing companies, the main producers are the southern states of the United States with annual sales listed in Table 6 [75]. The decrease in sales can be explained mainly by its reduced use in household disinfectants [65]. The most important pine oil-importing countries are Canada, Brazil, the United Kingdom, and Germany.

Table 6. Annual production and sales of pine oil in the southern United States

Year	Production, t	Export, t
1960	34 200	8 000
1970	48 400	13 000
1980	40 400	16 000
1990	28 500	6 600

Trade names (besides the common term pine oil): Arizole, Dertol, Flotation Terpene-S, and Unipine.

1. Introduction

Uranium, atomic number 92, is a radioactive element that is transformed into the stable element lead via many intermediate stages involving the emission of α- and β-radiation. Uranium has the probable electronic configurations $4s^2p^6d^{10}f^{14}$, $5s^2p^6d^{10}$, $6s^2p^6d^4$, and $7s^2$, and is a member of the actinides, in which the $6d$ shell is filled until uranium is reached, and the $5f$ shell is then filled from neptunium onward to $5f^{14}$. Natural uranium consists of three isotopes whose concentrations in different resources are usually the same, even to the fourth decimal: ^{238}U, 99.2762 at %; ^{235}U, 0.7182 at %; ^{234}U, 0.0056 at %. However, uranium from one deposit in Gabon (the Oklo mine) is exceptional [8], the proportion of ^{235}U being lower (see below [9]):

Expected ^{235}U content	0.711 wt %
Measured ^{235}U content (July 7, 1972)	0.7078 wt %
Absolute discrepancy	0.0032 wt %
Relative discrepancy	0.45 %
Accuracy of measurement	±0.0001 wt %

The somewhat lower percentage of ^{235}U in the Oklo deposit led to the discovery of natural reactors and the revelation that the first nuclear fission chain reaction was not brought about by humans in 1942 but by nature long before this. Since its discovery, the Oklo phenomenon has been investigated in great detail, and the results are documented in almost 100 papers. At least ten different reactor zones have been identified in Oklo. The individual reactors were active for 100 000 to 800 000 years. These periods of activity, which occurred 1.8×10^9 years ago, resulted in the release of 100×10^9 kW · h thermal energy, equaling the output of a large-capacity power reactor over a three-year period. These natural reactors are the only ones discovered thus far in the world. During these periods of activity, natural uranium still had a ^{235}U content of ca. 3 %; geochemical processes caused

the U content to increase to 30 % and higher. The thickness of the natural deposits reached 50 cm, and the presence of water as a moderator and coolant caused the configuration to become critical. The nuclear fission that then occurred was controlled by the properties of water. High power output led to evaporation of water, with consequent reduction of the moderating effect; lower power led to condensation and increased moderation. Decay products from earlier fission products and from the plutonium formed in the active zones of the natural Oklo reactor are still present without losses. This shows that these elements have not been dispersed but have been immobilized by simple geological barriers.

2. History

Uranium was discovered in 1789 by Martin Heinrich Klaproth, who extracted it from pitchblende. He precipitated the yellow uranate and reduced this with charcoal, but obtained only a black oxide, probably UO_2. In 1790, he named the putative metal uranium after the planet Uranus, which had been discovered in 1781 by Herschel. In 1841, E. M. Peligot reported that he had obtained uranium metal by thermal reduction of anhydrous uranium tetrachloride with potassium in a platinum crucible. In 1856, he succeeded in producing the pure metal in compact form by reducing uranium tetrachloride with sodium under inert conditions. A worth-mentioning quantity of uranium metal was put on display at the Paris World Exhibition of 1867.

In the 1890s, H. Moissan developed new processes for producing metallic uranium. He obtained the purest metal (>99 % uranium) by electrolysis of sodium uranyl chloride. At the end of the 19th century, uranium found some almost unnoticed industrial applications, e.g., in glass and ceramics because of the beautiful colors of its different compounds.

The discovery of radioactivity by A. H. Becquerel on March 1, 1896, resulted from experiments with uranium. The fluorescence and phosphorescence of uranium compounds had been studied from about the mid-1800s. Following the discovery of X-rays, the question arose of whether substances showing strong fluorescence or phosphorescence emitted penetrating rays of a similar kind. Becquerel exposed potassium uranyl sulfate to sunlight and observed that it emitted rays that darkened photographic plates. An interruption of these investigations due to cloud cover led to the discovery of intense darkening of the plates by uranium salts that had not been exposed to light. He concluded from this that uranium salts produced a special kind of radiation independent of light exposure.

The history of uranium is closely linked to the discovery of polonium and radium in pitchblende by P. and M. Curie in 1898. The induced fission of the isotope ^{235}U was discovered in 1938 by O. Hahn and F. Strassmann. This discovery was followed by intense research activity, that led to the first man-made nuclear chain reaction, which was brought about in Chicago by E. Fermi on December 2, 1942. World War II and U.S. decision to have a nuclear weapon led to intense activity in uranium research and nuclear development. Uranium enrichment plant based on the electromagnetic process was started in 1943 in Oak Ridge, Tennessee, followed a year later by another plant based on the gas diffusion principle.

After World War II, the search for uranium ores for the peaceful utilization of nuclear energy was intensified in most countries, and some large deposits were discovered. In the 1960s, military applications predominated; the peaceful use of nuclear energy gradually gained in importance in the late 1970s. Enriched uranium was required for the light-water reactors favored for energy production; thus, enrichment processes and techniques to manufacture fuel elements became important research and development topics. Enrichment by gas diffusion processes was used in the United States and France, whereas Germany, The Netherlands, and the United Kingdom developed a cooperative program based on three enrichment plants using the ultracentrifuge principle. The jet nozzle separation process, developed in Germany, is used in a demonstration plant in Brazil and in the Republic of South Africa.

Literature searches carried out for the present article have revealed that research and development of nuclear energy production and related technologies were largely complete in Western societies by the early 1980s. However, research continued into the technology of enrichment (laser and chemical processes), along with

fundamental research into the band structure of uranium.

3. Physical Properties

3.1. Radioactivity

The *natural uranium isotopes* (^{238}U, ^{235}U, ^{234}U) are α-emitters. Tables 1 and 2 show the decay chains of the two most important isotopes. These chains terminate with the nonradioactive isotopes ^{206}Pb and ^{207}Pb.

Artificial uranium isotopes are formed in a nuclear reactor (e.g., by irradiation or decay of transuranics). Thus, after reprocessing of spent fuel elements, the following uranium isotopes are found in the purified uranium for a uranium burnup of 36 GW · d/t and an initial enrichment in the fuel elements of 3.5 wt % (For a definition of burnup, see → Nuclear Technology):

^{232}U: concentration 0.71 mg per tonne U; half-life 74 a; → ^{228}Th
^{233}U: concentration 7.4 mg per tonne U; half-life 1.6×10^5 a; → ^{229}Th
^{234}U: concentration 137 g per tonne U; half-life 2.5×10^5 a; → ^{230}Th
^{236}U: concentration 4490 g per tonne U; half-life 2.4×10^7 a; → ^{232}Th

All four artificial isotopes are α-emitters with a certain amount of γ-emission and are transformed into the thorium isotopes indicated. Because of the comparatively short half-life of ^{232}U, associated γ-emission requires heavily shielded equipment for radiation protection. This hot-cell technology is also needed to handle the radioactive fission products in the reprocessing of spent fuel. Because it has an odd atomic number, ^{233}U is fissile by capture of a thermal neutron when it is reused in the reactor. However, ^{236}U in particular is purely a neutron absorber, so that on use of the reprocessed uranium, the fissile fraction (^{235}U) must be increased by ca. 0.15 % to compensate for neutron capture by the 0.45 % ^{236}U.

3.2. Modifications

The phase diagram of uranium is shown in Figure 1 [10, 11]. At atmospheric pressure, uranium occurs in three modifications with different crystal structures, depending on temperature [12]:

α-Uranium, $T < 942$ K, orthorhombic
Lattice constants: $a = 0.2858$ nm, $b = 0.5876$ nm, $c = 0.4955$ nm at 298.15 K.
β-Uranium, $T = 942 - 1049$ K, tetragonal
Lattice constants: $a = 1.0759$ nm, $c = 0.5656$ nm at 942 K (lower transformation point).
γ-Uranium, $T = 1049 - 1408$ K, body-centered cubic
Lattice constants: $a = 0.3524$ nm at 1049 K (lower transformation point).

Figure 1. Phase diagram of uranium [10, 11]
Ranges of the α-, β-, and γ-modifications and of the liquid are shown

The triple point of the three modifications is at 3.6 ± 0.2 GPa and 1078 ± 3 K [10]. Figures quoted for the *mp* at atmospheric pressure cover the relatively narrow range between 1398 K (1125 °C) [13] and 1408 K (1135 °C) [14]. These small discrepancies are due to extremely low levels of impurities that cannot be avoided completely. The *bp* is said to be 4407 K. The theoretical density of α-uranium is 19.13 g/cm^3, small variations in the experimental value again being due to impurities.

3.3. Mechanical Properties

In the γ-phase (1049 K $< T <$ 1408 K), the metal is soft, ductile, and easily worked. However, since this phase is readily oxidized in an oxidizing environment (e.g., air), uranium usually

ness is given in Brinell numbers (applied weight of 300 kg divided by the penetration area of a 10-mm steel sphere).

The modulus of elasticity is also very dependent on the history of the material; it ranges between 155 GPa (α-phase, rolled; β-phase, annealed) and 207 GPa (γ-phase, extruded).

3.4. Thermal Properties

The specific and molar heat capacities of the three uranium modifications are given in Table 5 [12].

Table 3. Mechanical strength of rolled uranium metal products annealed in the α- or β-region before measurement [15]

	Test temperature, °C	0.2 % Yield strength, MPa	Ultimate tensile strength, MPa	Elongation, %
Rolled at 570 °C

	150-kg weight	100-kg weight	
310 °C	36.6	109	341
490 °C	24.0	101	247
600 °C	22.0	99	240
720 °C	9.0	90	185
770 °C	0	92	152

Table 5. Specific and molar heat capacities of uranium modifications

	c_p, J kg^{-1} K^{-1}	C_p, J mol^{-1} K^{-1}
α-Uranium (298.15 K)	116	27.666
β-Uranium (942 K)	180	42.928
γ-Uranium (1049 K)	161	38.284

In the α- and β-phases, uranium is anisotropic; i.e., thermal expansion depends on direction. Thus, a crystal of α-uranium expands in only two directions and contracts in the third (Fig. 2). The expansion coefficients for α-uranium in the various crystal directions are given in Figure 3 [16, 17].

Figure 2. Dimensional change of α-uranium from 0 to 300 °C.
Original dimensions: $a = 0.2852$ nm; $b = 0.5985$ nm; $c = 0.4945$ nm; $\Delta a = +0.0015$ nm; $\Delta b = -0.0006$ nm; $\Delta c = +0.0339$ nm

Figure 3. Linear expansion coefficient of α-uranium [16]

For β-uranium in the range 959 – 998 K, the linear coefficients of expansion are

z-axis, 4.6×10^{-6} K^{-1}
x-axis, 23.0×10^{-6} K^{-1}
y-axis, 16.9×10^{-6} K^{-1}

The linear coefficient of expansion of γ-uranium is the same for all three axes (i.e., ca. 18×10^{-6} K^{-1}). The thermal conductivity of uranium at 298 K is 27.60 W m^{-1} K^{-1}.

3.5. Electrical and Electrochemical Properties [18]

The specific electrical conductivity of uranium has been determined by several authors. The variations in the value obtained [(3.0 – 3.38)$\times10^4$ Ω^{-1} cm^{-1}] are due to variations in the purity and history of the metal. The values determined for specific electrical resistance naturally show similar variation, the mean value at room temperature being ca. 30 μΩ cm. The specific electrical resistance increases with increasing temperature to ca. 55 μΩ cm at 873 K. At the transformation points of α- to β-uranium and of β- to γ-uranium, the curve shows a downward discontinuity but then rises again. The temperature coefficient of the specific electrical resistance in the range 273 – 373 K is (2.61 – 2.76)$\times10^{-3}$.

Uranium becomes superconducting at very low temperature, but the transition temperature T_c is very pressure dependent [10]. At atmospheric pressure, T_c has its lowest value (0.2 K); it reaches its highest value (2.25 K) at 1 GPa.

The standard electrode potential ϵ_0 for the reaction

$$2\,H^+ + 2\,e^- \rightleftharpoons H_2$$

$$2\,U^{3+} \rightleftharpoons 2\,U^{4+} + 2\,e^-$$

at 25 °C with a 1 mol/L solution of metal ions and a hydrogen electrode is with water −0.414 V, with a 1 mol/L $HClO_4$ solution −0.631 V, and with a 1 mol/L HCl solution −0.640 V. The thermoelectric potential with copper is ca. 5 mV [19].

3.6. Magnetic Properties

Uranium is paramagnetic. The paramagnetic susceptibility varies with temperature and exhibits discontinuities at the phase transformation points (Fig. 4). The specific magnetic susceptibility at 298 K is 1.66×10^{-6} cm^3/g.

Figure 4. Paramagnetic susceptibility of uranium

4. Chemical Properties

The freshly exposed surface of massive uranium metal has a silvery luster, but it is oxidized relatively rapidly in air. Within a few hours, the metal becomes covered with a thin oxide layer of iridescent colors and eventually turns black. The same mass of metal that is oxidized by steam at 593 K is oxidized by air only above 753 K. The enthalpy and the free energies of formation of oxides from the metal at 298 K are as follows [20]:

UO_2
$\Delta H = -1084$ kJ/mol
$\Delta G = -1029$ kJ/mol
U_3O_8
$\Delta H = -3565$ kJ/mol
$\Delta G = -3360$ kJ/mol
UO_3
$\Delta H = -1218$ kJ/mol
$\Delta G = -1138$ kJ/mol

Uranium metal powder is pyrophoric and burns or smolders very readily in air, sometimes spontaneously if the powder has a large enough surface area. Mechanical machining of uranium metal by turning, lathing, and drilling must be carried out with adequate work fluids for lubrication of the cutting tools and for cooling the chippings formed. To store the chippings, they are wetted with a special oil or burned promptly in a controlled manner to form U_3O_8. Uranium does not react with *hydrogen* at room temperature but combines readily with it at 498 K to UH_3, which decomposes again at 709 K. This behavior is utilized in the manufacture of the powdered metal from its compact form, in which UH_3 is produced as an intermediate. Also, to reduce the hazard involved in transporting tritium gas, it is absorbed by depleted uranium powder in flasks.

Uranium reacts very vigorously with *halogens* and *hydrogen halides*. It burns in fluorine gas to form UF_6 ("flame reactor"). The reaction with HF gas proceeds only to the UF_4 stage; reaction with aqueous HF leads to hydrated UF_4 ($UF_4 \cdot 0.75\ H_2O$, $UF_4 \cdot 2.5\ H_2O$). Uranium burns in a stream of chlorine to form UCl_6 and UCl_4. With bromine and iodine, it reacts to only UBr_3 and UI_3. With *sulfur*, grayish black US_2 is formed, which is stable up to 1273 K.

Powdered uranium reacts very vigorously with *water*; above 308 K the compact metal also reacts with water. Uranium is attacked vigorously by *dilute acids*, with the formation of salts. *Strong solutions of alkali* also attack the metal to form uranates.

5. Occurrence, Requirement, and Production Figures

5.1. Occurrence

The mean concentration of uranium in the earth's crust is 2×10^{-4} wt %. For comparison, the abundances of cobalt, lead, and molybdenum are similar. Uranium is a typical lithophilic element, occurring mainly in the silicates of the earth's crust. Most of the uranium is distributed widely in small concentrations, both in acidic rocks such as granite, gneiss, and pegmatite, and in sedimentary rock such as schist and phosphatic ores. Basic rocks (basalt) have a lower uranium content than, for example, granite. The wide distribution of uranium and the low degrees of enrichment in ores compared with other metals of similar abundance are the result of its ability to form a wide range of chemical complexes. Uranium occurs in more than 100 minerals; those of industrial importance are listed in Table 6.

Table 6. Uranium minerals of industrial importance *

Mineral	Chemical formula	Origin
Oxides, hydrates, simple silicates (uranium, completely or primarily tetravalent)		
Pitchblende	$x\ UO_3 \cdot y\ UO_2$	Canada, Congo, Western and Central Europe
Uraninite	UO_2 (with UO_3)	Canada, Colorado Plateau, Argentina
Coffinite	$x\ USiO_4 \cdot y\ U(OH)_4$	Colorado Plateau
Uranothorite	$x\ ThSiO_4 \cdot y\ USiO_4$	Canada, Madagascar
Complex deposits of uranium oxides with rare earths (titanates, etc.)		
Brannerite	$(U, Ca, Fe, Y, Th)_3Ti_5O_{16}$	Canada
Betafite (similar to ampangabeite)	$(U, Ca)(Nb, Ta, Ti)_3O_9 \cdot x\ H_2O$	Madagascar
Davidite	$(Fe, \text{rare earths}, U, Ca, Zr, Th)_x (Ti, Fe^{3+}, V, Cr, Y)_yO_z$	
Secondary minerals with hexavalent uranium		
Gummite	$UO_3 \cdot x\ H_2O$ (also silicate, phosphate, of indefinite composition)	
Uranophane	$CaO \cdot 2\ UO_3 \cdot 3\ SiO_2 \cdot 6\ H_2O$	Colorado Plateau, Argentina
Schroeckingerite	$Na_2O \cdot 3\ CaO \cdot UO_3 \cdot 3\ CO_2 \cdot SO_3 \cdot F \cdot 10\ H_2O$	Joachimsthal, Colorado Plateau, Argentina
Carnotite	$K_2O \cdot 2\ UO_3 \cdot V_2O_5 \cdot 3\ H_2O$	Colorado Plateau, Australia, Argentina
Tjujamunite	$CaO \cdot 2\ UO_3 \cdot V_2O_5 \cdot 8\ H_2O$	Turkestan, Colorado Plateau, Argentina
Autunite (torbernite)	$CaO \cdot 2\ UO_3 \cdot P_2O_5 \cdot 12\ H_2O$	France, Portugal, Colorado Plateau, Argentina

* Detailed information on uranium minerals is given in [21].

Some materials not regarded as true uranium minerals are the poorly defined uranium-containing bituminous products known as kolm (Sweden), thucholite (Sweden, Canada, Republic of South Africa), and asphalt or asphalite (Colorado Plateau, Argentina). An industrially important mineral which contains uraninite or pitchblende as accompanying mineral is mon-

Figure 5. Uranium concentration in important uranium minerals

azite. Large deposits of monazite are found in India and Brazil.

Large reserves are also present in seawater because of its enormous volume. However, the uranium level (ca. 3 ppb = 3 μg/L) is very low. Nevertheless, attempts have repeatedly been made since the 1950s to extract uranium from seawater. An enrichment factor of 10^5 has been achieved. However, the processes will be economical only if enrichment can be increased to ca. 10^6; the concentration would then correspond to that in a minable ore [22]. Uranium concentrations in the most important uranium-bearing ores in the earth's crust are shown in Figure 5 [23]. Approximately half of the annual uranium production comes from secondary minerals. One-third comes from conglomerates in which unweathered rock has been sedimented together with oxidized uranium. The remaining uranium production is from veins or lodes and syngenetic – sedimentary ore deposits.

5.2. Resources, Requirement, and Production Figures

A 1991 report with data valid for January 1, 1991, issued jointly by the Nuclear Energy Agency of the OECD and the IAEA, gives data on deposits, production, and uranium requirements for 44 countries [24]. This report, for the first time, includes countries from the former Eastern Bloc. Since then, the data from the former Eastern Bloc have become more precisely known and have been more thoroughly evaluated. The development of uranium supply and demand has also changed considerably. Thus considerable quantities of uranium from military projects are now available for civil nuclear energy generation as a result of worldwide nuclear disarmament. Hence OECD/NEA [25] and The Uranium Institute [26] have revised and re-issued their existing reports. The market perspectives have been studied with respect to how the ever-increasing gap between uranium demand and uranium production can only be bridged by the release of military reserves [27 – 29].

The known world uranium resources, classified according to the IAEA system by the state of exploration and anticipated costs per kilogram of uranium extracted, are listed in Table 7. Known reserves amount to 3.125×10^6 t, a figure that has been confirmed by more recent surveys of the Uranium Institute [26].

The reserves of the following countries are not included in the IAEA classification:

Table 7. World uranium reserves according to IAEA classification [24]; in 1000 t uranium *

On the basis of reports on estimated and speculative reserves, it is assumed that worldwide reserves amount to $(8 - 13) \times 10^6$ t of uranium. uranium.

Uranium Production of the Western Countries. Figure 6 shows the uranium production and uranium demand of the Western world in the period 1956 to 1995. In this part of the world, the uranium industry experienced its first boom in the early 1960s. At that time, almost the entire uranium production was consumed by the weapons programmes of the western nuclear powers (United States, United Kingdom, France). The civil uranium demand for nuclear power stations began in the late 1960s and early 1970s. This was stimulated by the expansion programmes that were established as a result of the oil crisis of 1973. However, the actual expansion in Europe and the United States failed to meet the planned level. Nevertheless, between 1975 and 1980, uranium production grew to meet the increased demand from civil nuclear energy generation. At this time, production of

Figure 6. Uranium production and demand of the Western world (1956 – 1996)

Figure 7. Uranium spot market price for European buyers (1968 – 1995)

uranium as a byproduct of phosphate-rock mining became important.

The dramatic decrease in production since 1989 is due to increasing oversupply. Thus, in 1980 the uranium production of the Western world was ca. 44 000 t U, but demand was only ca. 22 000 t U. While uranium production continued to decrease, the uranium demand of the civil nuclear energy programmes grew worldwide. The difference between supply and demand was covered by uranium from stockpiles. The price development for uranium shows clearly that sufficient quantities of previously produced uranium are reaching the market, since the uranium price has dropped (Fig. 7) despite the fact that production has failed to meet demand. Up to 1973, the uranium price remained at a constant 7 $/lb U but then increased greatly due to the oil crisis, reaching a peak of 45 $/lb U in 1976. The overcapacity existing at this time led to a price drop and eventual stabilization at ca. 23 $/lb in 1982. For the reasons discussed above, the uranium price fell slowly up to 1994 and then reached temporary stability at a low level.

Uranium Production of the Former Eastern Bloc. In the former Soviet Union, its satellite states, and China, ca. 630 000 t of uranium have been produced since the 1940s (Fig. 8).

Figure 8. Cumulated uranium production in the former Eastern Bloc and use of the material (1945 – 1994)

Prior to the political and economic liberation of the Eastern Bloc in 1989/90, the majority of the uranium produced in the Soviet sphere of influence was transported to the Soviet Union as a strategic material. Only Romania retained a few thousand tonnes for its CANDU reactor progamme. Of the uranium produced in the Soviet Union and imported from its satellites up to 1994, probably 450 000 t U was made available for military purposes, and 115 000 t U was used for the nuclear reactor programmes of the Soviet Union and Eastern Europe. Thus, today Russia should possess a stockpile of ca. 75 000 t U in the form of natural and enriched uranium. Figure 9 shows the uranium production of the CIS since 1991. Two of the largest producers, Kazakhstan and Uzbekistan, have essentially no nuclear energy programme, so that their entire production should become available to the world market in the form of exports.

Figure 9. Uranium production in the CIS (1991 – 1996)

Uranium Production Today. World uranium production in 1995 was ca. 34 200 t U, 75 % of which came from the Western countries and 25 % from Eastern Europe, the CIS, and China (Fig. 10). The 13 largest mines accounted for 70 % of world uranium production. The three largest Western uranium producers – Cogemá, Cameco, and Uranerzbergbau – were responsible for ca. 44 % of world uranium production. Figure 11 shows 1994 uranium production divided according to mine owners.

Figure 10. World uranium production in 1995 by countries

Figure 11. World uranium production in 1995, broken down by owners of mines

Figure 12. Projected uranium consumption for nuclear reactors [24]

Future Supply/Demand Pattern. Figure 6 shows uranium demand and uranium production up to 1996. Figure 12 shows an OECD/IAEA estimate of future uranium demand dating from 1991. World uranium demand in 1991 was 49 300 t U, and this was distributed between the continents as shown in Figure 12. On the basis of planned nuclear energy generating capacity, a uranium demand of ca. 77 700 t U is expected in the year 2010. New investigations of various reference scenarios of The Uranium Institute [26] give values between 70 000 and 80 000 t U. Schreiber [28] assumes a demand of less than 60 000 t U and predicts the uranium supply situation shown in Figure 13.

World uranium demand will increase slowly for about a decade, after which a downward trend can be expected if it is assumed that nuclear power stations are removed from the grid and not replaced when their licenses expire. This assumption is based on a projection of current energy policies. Figure 13 compares world uranium demand with maximum achievable production capacity. Production capacity is divided into potential projects, mines held in reserve, and plants in operation or for which concrete plans exist. Figure 13 shows that world uranium production could double by 2002, but also that the operating, planned, and potential projects will not be sufficient to cover the uranium demand of the nuclear power stations. Hence, in future the existing civil uranium inventories and those that become available from military programmes as a result of disarmament will have to be used to meet these demands.

6. Production

The production of uranium and its most important compounds is described in this chapter. Sec-

Figure 13. Figure 14. Uranium starting materials, intermediates, end products, and their uses

tion 6.1 is devoted to a review of starting materials, intermediates, and the most important uranium end products. Section 6.2 provides an overview of the most important processes used to convert crude ore to the end product. Section 6.3 contains detailed descriptions of all the processes mentioned in Section 6.2.

6.1. Uses of Uranium and Uranium Compounds

Uranium starting materials, typical intermediates, and industrially important end products are indicated in Figure 14. In all cases, the intermediate product "yellow cake" is produced from uranium ore. The industrially most important end product is UO_2, which is the only nuclear fuel used in power station reactors, although *uranium carbide* (UC) is sometimes used in sodium-cooled fast breeder reactors because of its higher density and superior thermal conductivity compared with UO_2.

Uranium metal is used as the fuel in materials testing reactors and Magnox reactors. Because of its extremely high density, it is also used in depleted form for trimming weights in large aircraft. A Boeing jumbo jet contains 360 kg of depleted uranium metal. The high density of uranium metal also utilized in shielding materials for protection against radiation sources (e.g., in portable equipment for weld radiography and medical X-ray equipment).

U – Zr alloys are used as nuclear fuel in marine reactors and in research and materials testing reactors. *Hydrogenated U – Zr alloys* ($UZrH_x$) are used as combined fuel – moderator systems in spacecraft reactors. *Uranium silicides* could in principle be used as fuel in light-water reactors. However, uranium silicides are not utilized because undesired reactions with water, the cooling medium, can occur as a result of defects in the fuel elements. *Uranium – aluminum alloys* are used in materials testing and research reactors.

Uranium salts are now rarely added to ceramic products to produce luminous colors (e.g., in Merano glassware or tiles) because of the radiation problems involved.

6.2. From Ore to End Product – A Review of Processes

6.2.1. From Crude Ore to Yellow Cake

The industrial routes from crude ore to yellow cake are illustrated in Figure 15. Mined crude ores are prepared for leaching by crushing and grinding. The chemical leaching process is selected according to the mineralogical nature of the ore. Acidic ores are treated with dilute H_2SO_4, and alkaline ores with an aqueous solution containing sodium carbonate and

Process step	Acidic ores	Alkaline ores	Phosphate rock
Classification	Screening		
Crushing, grinding	Mechanical crushing and grinding		
Leaching	Acid leaching with dilute H_2SO_4	Alkaline leaching with Na_2CO_3 and $(NH_4)_2CO_3$	Acid treatment
Solid–liquid separation	Filtration, multistage decantation, separation by hydrocyclones		
U extraction	Ion exchange, solvent extraction, Eluex process		Oxidation–reduction stripping process
Precipitation	By ammonia or magnesium hydroxide	By 50% sodium hydroxide	By $(NH_4)_2CO_3$ to form ammonium uranyl carbonate (AUC)
	Yellow cake ← Yellow cake	Yellow cake	AUC

Figure 15. From crude ore to yellow cake or ammonium uranyl carbonate (AUC)

Yellow cake

Process step	Wet process			Dry process
Pretreatment	Dissolution in HNO_3			Size reduction and preliminary purification
Wet purification	Solvent extraction

Filtration	Yes	Yes		
Calcination	ADU → UO_2	AUC → UO_2	UO_3 → UO_2	Reduction to UO_2
Conversion to UF_4	$UO_2 + 4HF \rightarrow UF_4 + 2H_2O$			
Conversion to UF_6 Dry purification	$UF_4 + F_2 \rightarrow UF_6$			Fractional distillation of UF_6
UF_6				UF_6

Figure 16. From yellow cake to UF_6

sodium bicarbonate. Phosphatic ores are treated with acid.

Solid – liquid separation of leached ore is achieved by standard processes such as filtration, multistage decantation, and hydrocyclone separation; uranium is recovered from the solution by ion exchange or solvent extraction. Combining these two techniques, as in the Eluex process, is also advantageous. Yellow cake is then produced by precipitation from the acid liquor with ammonia or $Mg(OH)_2$ or by precipitation from the alkaline liquor with NaOH.

Uranium is obtained as an accompanying element from phosphatic ores in which the uranium

content is very low (see Section 5.2). After acid treatment, uranium is purified and recovered by the stripping process. Uranium is precipitated as ammonium uranyl carbonate (AUC).

6.2.2. From Yellow Cake to UF_6

In the wet treatment process (Fig. 16), yellow cake is dissolved in HNO_3 and purified by solvent extraction. The resulting solution of uranium in nitric acid can then be reacted chemically to form UO_2 or UO_3 by using either the ammonium diuranate (ADU) or the AUC process, or by denitrating evaporation.

UO_2 is converted into UF_6 in two stages: first UF_4 is produced by treatment with HF; UF_4 is then converted into UF_6 by treatment with fluorine gas. In principle, yellow cake can also be processed in the dry state. After size reduction and preliminary purification, yellow cake is calcined to form UO_2, which is then converted into UF_6 as described above. However, the dry UF_6 so obtained must then be purified by fractional distillation.

6.2.3. From UF_6 to the Nuclear Fuel UO_2

If UF_6 (Fig. 17) is to be converted to the nuclear fuel UO_2 for light-water reactors, an enrichment process must be carried out for reasons of reactor physics until the ^{235}U isotope content is between 2 and 6 %. Enrichment processes commonly used include the diffusion process, the nozzle process, and centrifugation.

Enriched UF_6 can be processed by either wet methods (e.g., AUC, ADU) or dry methods [e.g., Integrated Dry Route (IDR), Direct Conversion (DC), General Electric Dry Conversion (GECO)] to obtain UO_2 powder. After chemical conversion and before pelletization, the powder must be pretreated (except in the case of precipitation by the AUC process). Only after pretreatment do the various steps of pelletization (compression, sintering, and grinding) give an end product with the desired spectrum of properties.

6.3. Detailed Description of the Processes

6.3.1. Digestion and Leaching of Ores

Before ore digestion appropriate pretreatment is essential. This includes size reduction for which several stages are necessary. In the first stage, lumps of ore ca. 1 m in diameter are passed through gyratory or jaw crushers with a power consumption of 250 – 350 kW. These reduce the ore to lumps of ca. 200 mm diameter. Cone

UF_6

Process step	Process description				
^{235}U enrichment	Diffusion, centrifugation, nozzle separation, laser process				
Conversion to UO_2 powder	Wet processes		Dry processes		
	AUC	ADU	IDR	DC	GECO
Powder preparation	None	Milling, compaction, granulation			
Pressing of green pellets	Mechanical pressing, usually with rotary pelleting machine				
Sintering	Reductive sintering in H_2 atmosphere, also pilot stage oxidative-reductive process				
Surface grinding	Centerless grinding to final dimensions				

UO_2 pellets

AUC = Ammonium uranyl carbonate; ADU = Ammonium diuranate; IDR = Integrated Dry Route; DC = Direct Conversion; GECO = General Electric Dry Conversion Process

crushers with a power consumption of 30 – 40 kW are used in the second stage, giving pieces of ore ca. 65 mm in diameter. Particle sizes of <10 mm are obtained in the third stage, in which fine cone crushers or roller crushers with power consumption of 15 – 20 kW are used [30, 31]. This degree of size reduction is adequate with most types of ore for which the much more usual sulfuric acid process is used. Finer grinding is necessary only for alkali treatment. Here screen mills and ball mills are used in succession to reduce the particle size of the ore to ca. 0.5 mm.

Consideration of the economics of the complete process of grinding and chemical treatment must include the question of whether preliminary removal of worthless material (gangue) might be beneficial. However, except for visual hand sorting of lump materials, no industrial process has thus far been used. Pilot-scale experiments in Elliot Lake, Canada, have been reported (Table 8) [32].

Table 8. Separation methods: amounts of worthless material removed and consequent uranium loss [32]

Method	Worthless material removed, wt %	U_3O_8 loss, wt %
Flotation after grinding to <0.3 mm	62 – 80	8
Gravitational method	ca. 35	8
Radiometry method	ca. 20	8
Magnetic separation	ca. 85	14

6.3.1.1. Acidic Ores

Dilute sulfuric acid is always used for the acid treatment of ores. The rate of dissolution depends on acid concentration, temperature, and surface area of the ore particles. If the ore contains feldspar and clay, highly concentrated acid should not be used since it will dissolve aluminum silicates. If the particles are ground too finely, clarification of the cloudy solution can present some problems. If tetravalent uranium is present, an oxidizing agent (sodium chlorate or manganese dioxide) is added to the liquor, with dissolved iron acting as a catalyst. The following reactions occur during the dissolution process:

$$UO_3 + 2\,H^+ \rightarrow UO_2^{2+} + H_2O$$

$$UO_2 + 2\,Fe^{3+} \rightarrow UO_2^{2+} + 2\,Fe^{2+}$$

$$UO_2^{2+} + SO_4^{2-} \rightarrow UO_2SO_4$$

At higher acid concentration, complex anions such as $[UO_2(SO_4)_3]^{4-}$ are also formed, but these do not cause problems in later processing.

6.3.1.2. Alkaline Ores

Alkaline ores require treatment with alkaline solutions. Alkaline leaching is considerably slower than acid leaching, but is more effective for ores in which the gangue materials contain calcium compounds or other acid-consuming components. For alkaline treatment the ore must be more finely ground. Since carbonate solution does not attack this type of gangue, uranium is dissolved much more selectively than when acidic solutions are used, and the subsequent concentration stage is easier. The dissolution of uranium is due to the formation of a tricarbonato complex:

$$UO_3 + Na_2CO_3 + 2\,NaHCO_3 \rightarrow Na_4\left[UO_2(CO_3)_3\right] + H_2O$$

The above ratio of carbonate to hydrogencarbonate should be maintained. If tetravalent uranium is present, oxygen is used as an oxidizing agent, and higher temperature and pressure are applied. This oxidation is catalyzed by copper sulfate and ammonia.

6.3.1.3. Digestion of Phosphate Rock

Uranium is present in phosphate rock at a mean concentration of 100 – 150 mg/kg. Florida phosphate rock, for example, contains 110 mg/kg uranium. Total uranium reserves in phosphate rock are currently estimated at ca. 7.1×10^6 t [24], which is nearly twice as much as the world reserves with beneficiation costs of <$ 130 per kilogram uranium.

Most phosphate rock minerals are members of the apatite group, having the typical composition $Ca_{10}(PO_4,CO_3)_6(OH,F,Cl)_2$, in which calcium is replaced to a small extent by U^{4+}, which is of similar size (U^{4+}, 0.097 nm; Ca^{2+}, 0.099 nm). The presence of uranium is due to the formation of phosphate deposits from seawater, which contains 3 µg/L uranium. In the presence of organic reducing agents or Fe(II) ions, U(VI)

is reduced to U(IV), which is incorporated into the apatite lattice.

When apatite is treated with dilute sulfuric acid at 80 – 135 °C to form crude phosphoric acid, uranium also goes into solution. However, if apatite is treated by the dry method or with concentrated sulfuric acid to form superphosphate, uranium is not dissolved but remains in the product. In Israel (only), uranium is first dissolved with hydrochloric acid when using the dry method. Two processes for extracting uranium from phosphoric acid solution have been put into practice, oxidation stripping and reduction stripping.

6.3.2. Treatment of the Liquor

Uranium can be removed from the liquor by ion exchange, solvent extraction, or a combination of the two processes known as the Eluex process. Undissolved solids, which would have a detrimental effect, are usually removed first from the liquor by sedimentation or decantation, or with hydrocyclones, filters, or centrifuges. The best process is vacuum filtration using plane, band, or drum filters, because the solution should be diluted as little as possible by washing of the filter cake.

Whereas slight cloudiness is tolerable for the ion-exchange process, the liquor must be clarified as much as possible before solvent extraction is carried out, because the expensive extraction agent can be lost by adsorption by the solids, which can lead to environmental pollution.

6.3.2.1. Uranium Recovery by Ion Exchange

Anionic complexes of uranium are present in both acid and alkaline uranium solutions. Strongly basic ion exchangers are generally used to extract these complexes:

$$4\,\mathrm{RX} + \left[\mathrm{UO_2(SO_4)_3}\right]^{4-} \rightleftharpoons \mathrm{R_4}\left[\mathrm{UO_2(SO_4)_3}\right] + 4\,\mathrm{X^-}$$

$$4\,\mathrm{RX} + \left[\mathrm{UO_2(CO_3)_3}\right]^{4-} \rightleftharpoons \mathrm{R_4}\left[\mathrm{UO_2(Co_3)_3}\right] + 4\,\mathrm{X^-}$$

where R denotes the matrix and X the functional basic group of the ion exchanger.

The pH is adjusted to 1.5 – 2 in sulfuric acid solutions and to 9 – 10 in alkaline solutions for the ion-exchange process, which can be operated batchwise (fixed-bed process) or continuously.

Fixed-Bed Process. In the fixed-bed process, cylindrical columns of diameter 2 – 3 m, height 4 – 5 m, containing 10 – 30 m^3 resin are used. The ion-exchange resin is loaded at a flow rate of 5 – 20 m^3/h and eluted at 1 – 5 m^3/h. The resin pebble bed usually consists of spherical particles of diameter 0.3 – 0.8 mm, but 2-mm-diameter granules may be needed to prevent blockage of the columns if solutions are incompletely clarified. For such solutions, the resin in pulp (RIP) process was developed, in which large resin granules are held in sieve baskets that are moved to and fro in a horizontal flow of unclarified liquor.

Elution can be carried out with 1 mol/L solutions of chlorides and nitrates. However, these anions interfere with subsequent loading of the resin, so elution with sulfates is often preferred. This proceeds more slowly but does not affect loading of the resin and is more cost-effective. The resin is first eluted with a 1 mol/L sulfate solution and subsequently treated with 10 % sulfuric acid or, in the case of alkaline uranium solutions, with 1 – 2 mol/L sodium carbonate – sodium hydrogencarbonate solution.

Continuous Ion-Exchange Processes. Several types of columns have been developed for continuous ion exchange. The first is exemplified by the *Higgins column*, which has been operated successfully in Texas and Wyoming since 1955 [33]. Resin is loaded as it is pushed slowly upward through the column. It is washed at the overflow at the top and then passed to elution columns. Similar columns have been used successfully by the Bureau of Mines in South Dakota. In 1977, the *Himsley column* was installed in Ontario, Canada, and the *Cloete-streat column* in South Africa. In the *Porter column*, which was installed in Namibia in 1978, uranium solution flows upward and overflows from the top into a second ion-exchange column at a slightly lower level. The laden resin is drawn off from the bottom by means of compressed air and fed via an intermediate tank into elution columns.

Although ion-exchange resins have been improved considerably, the trend now is toward solvent extraction or a combination of ion exchange and solvent extraction (Eluex process) because these processes give better selectivity and, hence, improved product purity.

6.3.2.2. Uranium Recovery by Solvent Extraction

Two types of extraction solvents are used: the first includes alkylated phosphoric acids and pyrophosphoric acids; the second, higher aliphatic amines. Both types are dissolved in inert hydrocarbons, mostly high-purity kerosene. The mechanism of extraction is based on ion exchange in the liquid phase. Tributyl phosphate (TBP), which is used in the production of high-purity uranium, cannot be used for liquid – liquid extraction of sulfuric acid liquors because neutral extraction media are not suitable for uranyl sulfate solutions.

Solvent Extraction with Phosphoric Acids. The following three phosphoric acids have been found suitable for extraction of uranium:

Isododecyl phosphate

Di(2-ethylhexyl) phosphoric acid (DEHPA), bis(2-ethylhexyl) phosphate [*298-07-7*]

Diiosooctylpyrophosphoric acid

In the extraction process, acidic hydrogen atoms of phosphoric acids are replaced by the uranyl ion. The exchange therefore also depends on the pH of the solution. The complexes formed are soluble in the organic phase. In contrast to extraction with neutral organophosphorus compounds, the anion of the uranyl salt is not extracted at the same time:

$$UO_2^{2+}\,(aq) + 2(RO)_2PO_2H\,(org) \rightarrow UO_2\left[PO_2(OR)_2\right]_2\,(org) + 2\,H^+\,(aq)$$

Extraction can be much improved by adding tributyl phosphate to the phosphoric acid (synergistic effect). Concentrated mineral acids or sodium carbonate solutions are used to strip uranium from the organic solvent.

Solvent Extraction with Amines. Newer uranium processing plants use mainly amines as extraction solvents. These are usually commercially available mixtures of either highly branched dialkylamines or straight-chain trialkylamines (see also → Thorium and Thorium Compounds, Chap. 4.2). Solutions of these amines in hydrocarbons have a strong affinity for uranyl sulfate and form addition complexes of the type $\left(R_3NH^+\right)_2\left[UO_2(SO_4)_2^{2-}\right]$ that are soluble in organic solvents. Uranium can be stripped from these solutions by simple ion exchange with solutions of the nitrate or chloride of sodium or ammonium. Sodium carbonate solutions, which are sufficiently basic to convert the amine salt into free base, can also be used.

Technique of Solvent Extraction. Only a few column types are suitable for solvent extraction; these include the rotating disk column and the *Scheibel column*. However, the most suitable type is the mixer – settler in its various forms. A continuous mixer – settler consists of a mixing chamber and a settling chamber. The mixing chamber is provided with an agitator to mix the two phases (aqueous and organic). The organic phase is fed by gravity from the preceding settling chamber into the inlet at the top of the mixing chamber, while the aqueous phase from the next settling chamber enters the mixing chamber from below. The mixed phases pass through an outlet at an intermediate height into the settling chamber in which the two phases separate. Thus, the phases flow countercurrently, and each mixer – settler constitutes one stage of the exchange process. Mixer – settlers are used for both the extraction and the stripping stages.

Four-stage mixer – settlers of various designs are used for industrial-scale solvent extraction (→ Liquid–Liquid Extraction). For example, in the Davy Power Gas mixer – settler, the mixed phases flow out centrally in upward direction. The Israel Mining mixer – settler contains lamellar internals to promote rapid phase separation [34]; these enable throughput rates to be improved by a factor of 20. The Lurgi Multi-Tray settler is aimed at a similar result [35]. Optimization of design and operation is described in [36].

6.3.2.3. Eluex Process

In the combined Eluex process, uranium is crudely separated by means of an ion-exchange resin, followed by solvent extraction [37]. The ion-exchange resin is designed so as to tolerate as much "cloudiness" as possible, and uranium is collected almost quantitatively. Breakthrough of foreign ions is acceptable since these are removed easily in the second (solvent extraction) stage. In this combined process, the first stage has the useful effect of increasing the concentration of uranium, with consequent reduction in the mass flow. This enables the second stage to be smaller by a factor of 20 – 30, and also improves the purification effect of this step as the uranium concentration in the feed is higher. An additional advantage is that the process can be used with relatively low uranium concentrations in the leach liquor (low-grade uranium ore). Thus, for example, the ion-exchange stage increases the concentration of a starting solution containing 0.02 – 0.5 g/L U_3O_8 to 9 – 12 g/L U_3O_8 and reduces the mass flow by the same factor. Four industrial plants processing 1000 – 1200 t/d ore are operating in the United States [38]. In the Republic of South Africa, the technique was developed in 1963 under the name "BuMex Process", and full-scale operation followed.

6.3.3. Production of Uranium Ore Concentrate

6.3.3.1. From Precipitation to Yellow Cake Production

Solutions obtained by the above processes contain uranium in the form of its sulfate or the carbonato complex $Na_4[UO_2(CO_3)_3]$. Uranium is precipitated from this as a uranate by addition of base, filtered, and dried. The uranium concentrate obtained, known as "yellow cake" because of its color and form, is the basic material for the production of nuclear fuels. Commercial uranium concentrates of various origins are listed in Table 9. Precipitation is carried out in large, agitated vessels. The precipitating agent for acidic, sulfate-containing solutions is ammonia or $Mg(OH)_2$, whereas carbonato complexes are precipitated by a 50 % solution of NaOH.

6.3.3.2. Processing of Phosphate Liquor and Precipitation of AUC

Oxidation Stripping Process. In oxidation stripping, U(VI) is first converted into U(IV) by adding Fe(II) salts to the phosphoric acid; uranium is then extracted from the orthophosphoric acid by mono- and dioctylphenyl esters mixed with kerosene. Stripping is by oxidative treatment with phosphoric acid and sodium chlorate ($NaClO_3$). The U(VI) is again extracted from the stripping solution at 40 – 50 °C, this time by trioctylphosphine oxide (TOPO) and 2-ethylhexyl phosphate (DEHPA) dissolved in kerosene; it is then reductively stripped from this extract by addition of Fe(II). Multiple recycling of the stripping solution gives an enrichment factor of 40. The stripping solution is then reoxidized by $NaClO_3$ and extracted with DEHPA – TOPO – kerosene. Phosphoric acid is washed out of the extract, which is then stripped with $(NH_4)_2CO_3$ solution. An excess of ammonium carbonate is added in the cold to the complex salt solution obtained, precipitating ammonium uranyl carbonate, $(NH_4)_4UO_2(CO_3)_3$. This is filtered off, washed, and calcined to give UO_{2+x}.

Reduction Stripping Process. Reduction stripping proceeds in an almost identical manner, except that only one extraction medium (DEHPA – TOPO – kerosene) is used. Uranium from the first stage is thus not reduced but extracted as U(VI). Both stripping stages are therefore reductive. Uranium does not require further purification in these cases and is usually purer than normal yellow cake.

6.3.4. Final Purification of Uranium Concentrate

6.3.4.1. Dissolution of Yellow Cake

Yellow cake produced by mining companies is not a single chemical substance, but a mixture of uranates. Its composition depends on the mined ores, as mentioned above, and on the chemistry of the treatment process suitable for those ores. The uranium content and the nature and concentration of impurities vary. However, the manufacture of nuclear fuel requires a product of high

purity and constant composition, and the fine purification processes are intended to achieve this aim.

On an industrial scale, wet processes are used mainly to treat yellow cake, which must therefore first be brought into solution. This is achieved with hot nitric acid, which dissolves the uranium as uranyl nitrate. Impurities settle out to some extent or may also be dissolved as nitrates.

6.3.4.2. Extractive Purification

In the extractive stage of purification, uranium is separated from the accompanying impurities as far as possible. Removal of elements with a high cross section for thermal neutrons (e.g., boron, rare earths, cadmium, and lithium) is especially important.

Purification is carried out by dissolving the uranium concentrate in nitric acid and extracting uranium with selective solvents. TBP diluted with hydrocarbons is used in most purification plants. A complex is formed according to

$$UO_2^{2+}\,(aq) + 2\,NO_3^-\,(aq) + 2\,TBP\,(org) \rightleftharpoons UO_2(NO_3)_2{\cdot}2\,TBP\,(org)$$

The complex is neutral, anhydrous, and undissociated, and has a higher solubility in the organic than in the aqueous phase. The uranyl nitrate solutions contain an excess of free nitric acid (sometimes nitrates of alkali metal, alkaline-earth metal, or aluminum are added), which has a salting-out effect and improves the distribution coefficient between the organic and inorganic phases. The tributyl phosphate solution is then treated with pure water, and uranyl nitrate is transferred back to the aqueous phase. The distribution coefficient is temperature dependent, and hot water (50 – 60 °C) is preferred for this stripping process.

Other heavy-metal nitrates can also form complexes with TBP. The more completely the amount of tributyl phosphate present in solution is bonded to $UO_2(NO_3)_2$, the smaller is the extent to which other heavy-metal nitrates are extracted. Therefore, a high degree of saturation of tributyl phosphate with uranyl nitrate is necessary. To reduce the density of tributyl phosphate (which is close to that of water) and to lower its relatively high viscosity, it is diluted with inert, saturated hydrocarbons. Kerosene and *n*-hexane are generally used, giving solutions that usually contain 25 – 35 % TBP.

Harmful impurities in uranium solutions include gypsum and soluble silica, which can be deposited in the solvent extraction apparatus and

reduce the efficiency of extraction. Also, some anions, especially sulfate and phosphate, cause problems by forming complexes with uranium. These complexes are not extracted and therefore lead to uranium losses. Fluorides and chlorides in the presence of nitric acid can cause severe corrosion of the vessel material.

Tributyl phosphate also contains impurities that interfere with extraction. Some of these are present in the commercial product as supplied; others are formed by chemical attack and by radiation. The main impurities are dibutyl- and monobutylphosphoric acids. Although dibutylphosphoric acid extracts uranium more effectively, it is less selective than tributyl phosphate (i.e., impurities are extracted at the same time). These make the stripping of uranium more difficult. Acids can be removed by washing them out of the tributyl phosphate (e.g., with sodium hydroxide solution).

Technique of Solvent Extraction. The concentrate is dissolved in nitric acid, and the concentrations of uranium and nitric acid in the unfiltered solution are adjusted to the desired values, usually 250 – 350 g/L uranium and 1 – 3 mol/L free nitric acid. Before being fed to the solvent extraction plant, the solution is filtered in some plants. Various types of extractors (Fig. 18) are used in solvent extraction plants. Pulsed sieve tray columns are the most popular, but mixer –settlers are also used in some cases. Pulsed columns and mixer – settlers are used both for solvent extraction and for washing and stripping. The columns contain perforated stainless steel plates ca. 50 mm apart. The holes are 3 – 5 mm in diameter, and the total area of all the holes is ca. 23 – 25 % of the area of the plate. In the first column, uranyl nitrate is extracted by the solvent (25 % TBP in kerosene). The volume ratio of the two phases is set such that maximum saturation of the organic phase with uranyl nitrate, together with almost quantitative extraction (>99.9 %), is achieved. In the second column (washing column), the organic phase is washed with a small amount of deionized water to remove impurities extracted at the same time. A volume ratio of organic phase : water = 10 : 1 is adequate. In this washing process, uranium is also partly transferred into the washing water. This solution is therefore recycled to the process. After the organic phase has been washed, it passes into the stripping column where uranyl nitrate is stripped out by hot (60 °C) deionized water. After treatment of the organic solvent with Na_2CO_3 to remove hydrolysis products of tributyl phosphate and the remaining uranium (a step not always included in the process), the organic solution is fed back to the first column.

6.3.5. Production of UO_3 and UO_2 from Purified Uranyl Nitrate Solution

Two different methods have been developed for the production of UO_3 and UO_2 from uranyl nitrate solution. In the first of these, the uranyl nitrate solution is evaporated until uranyl nitrate hexahydrate is completely crystallized; and this is then converted into uranium trioxide by thermal decomposition. Alternatively, uranium is precipitated in the form of an insoluble compound, and this precipitate (usually an ammonium salt) is converted into uranium trioxide. Common to both processes is reduction of the uranium trioxide UO_3 obtained to uranium dioxide UO_2. The two processes are compared in Figure 19.

Figure 19. Methods for the production of UF_6

6.3.5.1. Evaporation of Uranyl Nitrate Solution and Denitration by Thermal Decomposition

Solutions of uranyl nitrate are evaporated until uranyl nitrate hexahydrate, $UO_2(NO_3)_2 \cdot 6\,H_2O$, begins to crystallize. Further evaporation leads to the liberation of nitrogen oxides and water:

$$UO_2(NO_3)_2 \cdot 6\,H_2O \rightarrow UO_3 + NO + NO_2 + O_2 + 6\,H_2O$$

This decomposition and the phase diagram of the hydrated uranyl nitrate have been investigated thoroughly. The phase diagram (Fig. 20) shows that the hexahydrate and the trihydrate have incongruent melting points at 60 and 113 °C, respectively. The uranyl nitrate – water system is stable up to 184 °C, the melting point of the dihydrate. Above this temperature, decomposition to uranium trioxide occurs with liberation of nitrogen oxides. This reaction becomes much more rapid above 300 °C. Since uranium trioxide loses oxygen above 430 °C [39], 400 °C is considered the optimum temperature for producing UO_3. In order not to reduce the reactivity of UO_2 in later process steps (reduction, sintering, or hydrofluorination), avoiding higher temperatures, at which the U_3O_8 phase could be formed, is desirable.

Figure 20. Phase diagram of the system $UO_2(NO_3)_2 - H_2O$

Evaporation. The design of evaporation plants depends on the initial concentration of solutions to be evaporated. Since nitric acid at low concentration (up to 0.05 mol/L) is handled, the construction material is stainless steel. Vertical tube evaporators and evaporation tanks heated by internal steam pipes are commonly used. The final concentration of uranyl nitrate for the subsequent denitration stage is established by means of temperature control. Thus, a temperature of 120 °C corresponds to a uranium concentration of ca. 1000 g/L, and 143 °C to ca. 1285 g/L, the solution fed to the denitration stage being produced at a concentration between these two. The melting point of the less concentrated solution is 60 °C, and that of the more concentrated solution 116 °C. Because these melting points are relatively high, care must be taken to prevent the melt from solidifying in any part of the system (e.g., by heating the pipework). Concentrated uranyl nitrate solution is stored in heated tanks before being pumped to the denitration stage.

Denitration. *Batchwise denitration* was carried out in stainless steel pots containing fairly powerful agitators but the batch process is rarely used today.

Continuous Denitration. The continuously operating furnace first used in 1956 in a plant in Hanford (Washington) consists of a *horizontal trough* with a central stirring device. Uranyl nitrate is fed via rotameters through the inlets to the decomposition trough, and the UO_3 formed flows out over a weir into a powder receiving vessel.

The temperature in the bed of powder largely determines the water and nitrate content of the powder. The nitrate content varies between 1.1 % at 242 °C and 0.02 % at 454 °C. At these temperatures, the water contents are 2.6 and 0.1 %, respectively. Here, too, higher bed temperature leads to powder with lower reactivity.

The mean particle diameter of the powder is ca. 150 µm. In comparison to UO_3 powder produced by other processes, all powder produced by thermal decomposition of uranyl nitrate has a relatively high bulk density (ca. 3.5 – 4.3 g/cm^3) (i.e., the individual particles are very dense).

In the course of development work on equipment, Argonne National Laboratory started to develop a *fluidized-bed denitration furnace* as early as 1953. Fluidized-bed furnaces are now used widely not only in this stage but also in the reduction stage, for example.

Denitration is carried out by spraying uranyl nitrate solution onto a fluidized bed of hot particles of UO_3. Carrier air is introduced from below through a porous metal filter and into the reaction tube where it fluidizes the bed of powder. Gaseous reaction products pass through sintered metal cartridges at the top of the reaction tube, and the nitrogen oxides are subsequently

absorbed in water. The mean particle diameter is 150 – 200 µm. A fluidized-bed reactor of a type still often used today is illustrated in Figure 21.

6.3.5.2. Precipitation of Uranium by the ADU and AUC Processes

The sparingly soluble compounds ammonium diuranate (ADU), $(NH_4)_2U_2O_7$, ammonium uranyl carbonate (AUC), $(NH_4)_4[UO_2(CO_3)_3]$ and uranium peroxide, $UO_4 \cdot 2\,H_2O$, can all be used to precipitate uranium. All three compounds form uranium trioxide on thermal decomposition in air, although precipitation of uranium peroxide is now rarely used industrially.

The ADU process was the first to be operated on an industrial scale and is still used widely today [40]. Precipitation of uranium from aqueous solution by ammonia gives a nonstoichiometric precipitate whose composition does not correspond to the chemical formula. Instead, the molar ratio NH_3 : U varies between 0.3 and 0.45. The properties of ammonium diuranate and of uranium dioxide produced from it can be influenced within limits by changing the operating conditions. Important parameters that determine particle size and particle-size distribution include temperature, precipitation time, initial concentration, and intensity of agitation. A relatively large size of agglomerated particles is obtained by using urea as the precipitating agent [41] or by passing a mixture of NH_3 and air into the solution [42]. Depending on the plant, precipitations can be carried out continuously or batchwise. The precipitate is separated from the mother liquor with the aid of continuous filters and centrifuges.

AUC Process [43, 44]. The AUC process was developed for precipitating uranium from fluorine-containing solutions (from the hydrolysis of UF_6) because the fluoride contained in precipitated AUC (produced by addition of NH_3 and CO_2) can be removed nearly completely by washing, in contrast to ammonium diuranate precipitated by NH_3. Because of the high-quality UO_2 powder obtained from the precipitated product, this process was also used for uranyl nitrate solutions. The equations of these reactions are as follows:

$$UF_6 + 5\,H_2O + 10\,NH_3 + 3\,CO_2 \rightarrow (NH_4)_4\left[UO_2(CO_3)_3\right] + 6\,NH_4F$$

$$UO_2(NO_3)_2 + 3\,H_2O + 6\,NH_3 + 3\,CO_2 \rightarrow (NH_4)_4\left[UO_2(CO_3)_3\right] + 2\,NH_4NO_3$$

Ammonia and carbon dioxide pass through a system of jets into a reaction tank filled with water, and uranyl nitrate solution is added at the same time at a controlled rate. The aqueous solution is pumped around a circulating system for the entire period during which reactants are

added. The temperature of the water and the suspension increases because of liberation of heat of solution and reaction. When it reaches 60 °C, the suspension is cooled to prevent excessive decomposition of the ammonium carbonate formed. After cooling to room temperature, the suspension is fed to a rotary disk filter, and after washing the precipitate with water, residual water is removed by suction until the moisture content is ca. 8 %. If desired, the product can be dried further by washing with alcohol. The filter is discharged by rotating it while a knife fixed to a moving arm travels from the center to the edge of the filter over a period of up to 3 – 4 h, removing the filter cake in a thin layer. The powder is fed by a pneumatic suction device through the air lock of the fluidized-bed furnace.

6.3.5.3. Reduction of Precipitated Product to UO_2 Powder

Ammonium diuranate or ammonium uranyl carbonate can be reduced to uranium dioxide either immediately or after drying. The reduction temperature is 500 – 700 °C. Hydrogen or cracked ammonia (i.e., an N_2 – H_2 mixture) can be used as reducing agent. Most reducing furnaces used today are continuously or discontinuously operated fluidized-bed furnaces.

Batchwise Process. A discontinuously operated fluidized-bed furnace is used in the AUC process (Fig. 22). The precipitated product in powder form is fed in small portions of ca. 0.5 kg through a cellular wheel sluice into the furnace, where it decomposes to uranium dioxide in the hot, reducing atmosphere of the furnace. The gases liberated are passed through porous metal filter cartridges. Water vapor is used as the carrier gas for fluidization, and hydrogen is the reducing gas; these are fed through a fritted metal plate.

Continuous plants usually consist of several fluidized beds. The product is fed by a screw feeder into the first reactor where only partial reduction takes place; the powder then passes over an overflow into the second reactor where reduction is completed. *Moving-bed furnaces*, which are electrically heated cylindrical shafts through which a powder – granular material migrates continuously downward from above, produce a heterogeneous powder because of large temperature gradients in the furnace; these are now seldom used. However, *rotary kilns* are sometimes employed and, like fluidized-bed furnaces, are in widespread use for other process stages in the thermal treatment of uranium compounds.

6.3.6. Production of UF_4

Uranium hexafluoride has always been produced on an industrial scale via the intermediate UF_4, which is produced in a dry process by reaction of UO_2 with anhydrous hydrogen fluoride. If UO_3 is the starting material, it is first reduced to UO_2. Uranium hexafluoride is then produced by reaction of UF_4 with elementary fluorine.

6.3.6.1. Hydrofluorination of UO_2

The reaction

$$UO_2 + 4\,HF \rightleftharpoons UF_4 + 2\,H_2O \quad \Delta H_{298} = -178.3\,kJ/mol$$

is carried out at 300 – 600 °C, depending on the reactivity of the UO_2 powder and the desired bulk density of the UF_4 product. Some difficulties are encountered due to the reversible nature of the hydrofluorination reaction and the possibility that eutectic UF_4 – UO_2 mixtures may be formed that can lead to plastic flow and, hence, sintering at higher temperature. Uranium tetrafluoride always contains a small proportion of UO_2F_2 formed from the reaction of uranium trioxide with HF:

$$UO_3 + 2\,HF \rightarrow UO_2F_2 + H_2O$$

Fluidized-bed furnaces and rotary kilns are generally used to carry out the reaction. The LC reactor, which was developed in France, is of a special type (Fig. 23), part of which resembles a moving-bed reactor (a) in which granulated uranium trioxide is reduced to uranium dioxide. The latter is then converted to UF_4 by passing anhydrous hydrogen fluoride over it in the next part of the equipment (d), which has vertical and horizontal sections. The powder flows by gravity through the moving bed and is then propelled forward in the horizontal section by a built-in screw feeder.

6.3.6.2. Hydration and Hydrofluorination of UO_3

In a process developed by British Nuclear Fuels Limited (the BNFL process) [44], uranyl nitrate solutions are concentrated continuously and denitrated to form UO_3.

Reduction of UO_3 to UO_2 was formerly carried out in semicontinuous fluidized-bed reactors, and hydrofluorination of UO_2 to UF_4 in batch-operated fluidized-bed reactors. For economic and technical reasons, a change to continuous rotary kilns was made.

The so-called UTK process (uranium tetrafluoride in kilns) has three principal stages (Fig. 24):

1) Exothermic hydration:

$$UO_3 + x\,H_2O \rightarrow UO_3 \cdot x\,H_2O$$

2) Endothermic dehydration and exothermic reduction:

$$UO_3 \cdot H_2O + H_2 \rightarrow UO_2 + 2\,H_2O$$

3) Exothermic hydrofluorination:

$$UO_2 + 4\,HF \rightarrow UF_4 + 2\,H_2O$$

Figure 23. LC reactor for UF_4 production
a) Reduction section; b) Heating; c) Cooling; d) Hydrofluorination section

Uranium trioxide as produced by denitration in the fluidized bed consists of hard spherical particles with low surface area and inner porosity. To increase both of these parameters and thereby ensure rapid diffusion of the reacting gases, UO_3 is hydrated in jacketed vessels made of special steel. These contain screw feeders that

operate intermittently, bringing the powder into contact with metered quantities of steam. Careful control of contact time and temperature ensures that the product is a dry, free-flowing powder.

Hydrated UO_3 powder is reduced in stainless steel rotary kilns (b) containing a system of pushers and retaining rings to give intimate contact with the countercurrent flow of hydrogen. The UO_2 formed is fed pneumatically under nitrogen into the feeder tank (c) of the hydrofluorination stage. The reaction temperature over the entire length of the kiln must be controlled carefully to ensure complete reduction of the product without any decrease in its chemical reactivity during the endothermic dehydration and exothermic reduction. Waste gases leaving the kiln contain nitrogen, steam, and excess hydrogen; they are passed first through filters that remove suspended particles of powder and then through water-cooled condensers and a flame. The gases are then discharged into the atmosphere.

UO_2 is converted into UF_4 in a rotary kiln (h) containing similar powder feeding equipment, the material of construction being Inconel. Waste gases (nitrogen and small amounts of excess HF) are filtered and scrubbed with sodium hydroxide solution before being released to the atmosphere. The NaF solutions produced are treated with hydrated lime.

6.3.7. Production of UF_6 from UF_4

6.3.7.1. Process Description

The only processes used on an industrial scale involve the use of elementary fluorine. Uranium tetrafluoride reacts with fluorine according to

$$\mathrm{UF_4\,(solid) + F_2\,(g)} \rightarrow \mathrm{UF_6\,(g)}\,;\ \Delta H_{298} = -246\,\mathrm{kJ/mol}$$

The reaction proceeds fairly rapidly above 250 °C. Reaction temperatures of 400 °C are used for fluorination in fluidized-bed reactors, while flame reactors operate at 1100 °C.

If the conversion to UF_4 is incomplete, the product will contain UO_2 and UO_2F_2, which also react with elementary fluorine. Large amounts of fluorine are consumed in these reactions, so the concentration of these compounds in UF_4 should be kept low. All metallic impurities react to give fluorides in which the metals are at their maximum oxidation states. Nonvolatile fluorides (e.g., AlF_3, FeF_3, and ThF_4) remain behind with unreacted UF_4; the volatile compound UF_6 contains volatile fluoride impurities (MoF_6, VF_6, SiF_4, CF_4, SF_6, etc.). These impurities can be removed by distilling UF_6 and condensing it as a solid. For this, several condensers are used in series. Volatile fluorides of other elements contained as impurities (C, P, Si,

B, and S) can be removed without problem during crystallization of UF_6; nonvolatile fluorides remain behind as solids at the bottom of the reactor. Most of the UF_6 can be recovered between +5 and −15 °C in relatively large condensers; the remaining UF_6 is collected in much smaller condensers at ca. −50 °C. Uranium hexafluoride is then melted out of the filled condensation vessels and collected in storage cylinders.

The heat-exchange surfaces of the condensers consist of flat ribbed plates that are fixed with baffles to the coolant pipes and steam pipes to give good contact. The tubes are U-shaped to reduce thermal stress to a minimum and to enable the condenser contents to be removed easily from the vessel.

6.3.7.2. Chemical Reactors

Fluidized beds can be used for all stages of the process, i.e., the production of UO_3 and its further reaction to UO_2, UF_4, and UF_6. All of these are gas – solid reactions for which the fluidized-bed reactor is ideally suited, providing rapid mixing of the components and having only small temperature gradients within the bed volume.

Flame reactors, developed by Union Carbide Nuclear Corp., are also used. These reactors (Fig. 25) consist of a vertical Monel tube surrounded by a cooling coil, with a device at the top to give good distribution of UF_4, which is fed by a screw feeder. Fluorine, which is in excess, is fed through nozzles to the top of the reactor. Reaction of the two components produces a flame at ca. 1100 °C inside the reactor. The upper part of the reactor, where most of the reaction occurs, must be cooled to give a wall temperature between 450 and 540 °C. This both minimizes corrosion of the structural materials and prevents the formation of low-valence uranium fluorides.

6.3.7.3. Removal of Excess Fluorine from UF_6

To achieve complete fluorination of uranium, excess fluorine must be used; therefore, excess fluorine will still be present in the reaction gas after it has passed through the condenser. This fluorine comprises ca. 20 – 40 % of the reaction gas and must be removed in an additional chemical reactor. This is similar to the fluorination reactor and operates with an excess of UF_4. Not only is UF_6 formed, but also lower-valence intermediates such as UF_5, U_2F_9, and U_4F_{17}.

6.3.8. Complete Plant for Production of UF_6 from Uranyl Nitrate

6.3.8.1. French Process in Pierrelatte [45]

Uranyl nitrate solution (see Fig. 26) is pumped into a precipitation vessel (a) together with ammonia and water, which react to form ammonium diuranate. Temperature and pH are controlled during precipitation. The precipitate is

Figure 26. French process for UF_6 production
a) Precipitation; b) Filters; c) Mixer; d) Calcination and reduction; e) Hydrofluorination; f) Flame reactor; g) Primary crystallizers; h) Secondary crystallizers; i) UF_6 receiver

filtered off by using a vacuum drum filter (b) and is transferred from this to a mixer (c), which converts it into a pumpable slurry by utilizing the thixotropic properties of the material. Ammonium diuranate is calcined to UO_3 in the first rotary kiln (d) and then reduced by a countercurrent flow of hydrogen further down this kiln. Uranium dioxide passes through a seal into a second rotary kiln where hydrofluorination occurs. A third kiln containing a screw feeder completes this reaction. The HF required for fluorination is fed from the exit end of the third rotary kiln in countercurrent flow to the solid. The UF_4 formed is conditioned in drums and then burned in a flame reactor (a vertical Monel tube 4.40 m in length) to form UF_6. The solid byproducts UF_5 and U_2F_9, which are formed in very small quantities, are removed by a screw and recycled to the top of the reactor.

6.3.8.2. Allied Chemical Process

Unlike the processes described above, the Allied Chemical process does not include final purification of uranyl nitrate by liquid – liquid extraction. Instead, UF_6 is purified by distillation [46]

Figure 27. Flow diagram of an Allied Chemical UF_6 production plant
a) Tower reactor; b) Filter; c) Condenser; d) Scrubber; e) Fluorinator; f) Mill; g) Ash treatment

at a pressure and temperature above the triple point of UF_6 (64.05 °C at 151.1 kPa). Schematics of UF_6 production and distillation plants are shown in Figures 27 and 28, respectively.

6.3.9. Enrichment of ^{235}U

Three industrial processes are used for enrichment of uranium: the diffusion process, the ultracentrifuge process, and the less important jet nozzle process. Chemical enrichment, laser separation, and the plasma process are used on an experimental or laboratory scale. The three industrial processes employ gaseous UF_6. Chemical enrichment requires the uranium to be in solution. Two laser separation processes are in competition with each other. Metallic uranium is used in one of these, and gaseous UF_6 in the other. Metallic uranium is used in the plasma process as well.

6.3.9.1. Diffusion Process

Separation by diffusion occurs because isotopes diffuse through a semipermeable membrane at different rates owing to the $\sqrt{m}$ effect. A schematic diagram of the process is given in Figure 29 [47]. The separation factor is small (i.e., 1.002 – 1.004 per stage). Many separation stages (1000 – 1500) are arranged in series in cascade to give an integral separation effect. For improved maintenance and ease of replacement, 5, 8, 10, 16, or 20 separation cells are combined as a module. The heavier fraction (depleted in ^{235}U) that did not diffuse goes back to the previous stage. The heart of the separation cell is the

Figure 29. Schematic of a diffusion cell [47]

diffusion membrane, which usually has a tubular shape. Diffusion is accelerated by a concentration difference between the outside and the inside induced by a pressure. The pressure difference is 1 – 10 kPa, depending on the membrane material, and the operating pressure in a cell is 10 –30 kPa. Many materials have been tested as membrane materials, including Au, Ag, Ni, Al, Cu, Monel, Teflon, and Al_2O_3. Details of membranes are kept secret. They must be as thin as possible and have a pore size of 10 nm, but they must also have sufficient mechanical stability to withstand the pressure difference for years. One method of producing pores is to dissolve out a component of alloy foils (Ag – Zn, Au – Ag) selectively. Al_2O_3 membranes are produced from aluminum foil (13 – 30 μm thick) by anodically oxidizing it to completion in 5 – 10 % sulfuric acid and then heat treating at 500 – 530 °C. Water is evolved, and a porous membrane is formed with a permeability of ca. 0.1 $cm^3\ cm^{-2}\ s^{-1}$. In the EURODIF plant in Tricastin, France, diffusers (diffusion cells) and compressors have been joined to form a single unit. The main disadvantage of the diffusion process is the high energy requirement for the work of compression. For example, the EURODIF plant, which provides 10 800 t USW/a (tonnes of uranium separative work per year), requires ca. 3000 MW electric power, for which four nuclear power stations, each of 925 MW capacity, have been constructed [48].

6.3.9.2. Ultracentrifuges

In 1942, P. Harteck and W. Groth first used centrifuge technology to separate uranium isotopes. The countercurrent centrifuge is illustrated in Figure 30 [47]. The separation factor of 1.2 formerly achieved has now been increased to 1.5 in modern equipment of this type. In Germany in 1970, a trilateral centrifuge project among the United Kingdom, The Netherlands, and the Federal Republic of Germany was inaugurated (foundation of URENCO), and construction of three plants each with an enrichment capacity of 200 t USW/a was agreed upon. The German and Dutch plants are in Gronau, Lower Saxony, and Almelo, The Netherlands, respectively; the British plant is in Capenhurst,

United Kingdom. Over the long period of operation, 99 % plant availability has been achieved [49]. Ultracentrifuge plants of capacity >100 t USW/a are competitive with diffusion plants and have two important advantages:

1) The specific energy consumption using the centrifuge technique is 200 kW · h/kg USW.
2) The cascade for a low degree of enrichment (e.g., for light-water reactors) has only 15 – 20 separation stages, but diffusion equipment requires 1200 stages (EURODIF). A plant using the ultracentrifuge technique can be extended easily by the modular method using parallel connections.

Figure 30. Cross section of a centrifuge [47]
a) Housing; b) Vacuum; c) Magnetic holding device; d) Rotor; e) Electrical drive; f) Needle bearing

6.3.9.3. Nozzle Process

This process, which was developed by E. W. Becker in Karlsruhe, is the only one to which secrecy restrictions do not apply [50]. A modern nozzle with dimensional data is described in [51]. The separation effect is improved by addition of a light gas. The nozzle principle is illustrated in Figure 31 [47].

Figure 31. Schematic of the Brazilian nozzle separation system [47]
a) Compressor; b) Double deflecting system

A mixture of 4 % gaseous UF_6 and 96 % of a light carrier gas (e.g., H_2 or He) is expanded in the first jet. Due to the flow deflection in the carrier stream the heavier uranium isotopes become enriched in the outer flow region. Subsequently the outer flow region is separated by specially designed separation geometry from the inner flow region. The second jet works similarly and is used to improve the efficiency of the stage.

The production of enriched uranium for light-water reactors requires several hundred stages in a cascade; i.e., the separation effect (1.015 – 1.026) is better than that obtained by the diffusion process and worse than that obtained by ultracentrifugation. The energy requirement is comparable to that of the diffusion process since high energies of compression are required. The process is operated on an industrial scale in Brazil and the Republic of South Africa (the Helikon process).

6.3.9.4. Chemical Enrichment

The principle of chemical enrichment is based on the fact that in some chemical exchange processes (e.g., $UX + Y \rightleftharpoons UY + X$), different uranium isotopes have different tendencies to bond to substances X and Y. This mechanism is based on small differences in the preferred mean oxidation states of the particular isotopes in the given reaction environment. For industrial operation, the reaction must be rapid; the separation factor for the reaction must be acceptable; and the reverse reaction must occur readily. A pilot plant in operation in Japan [52] depends in principle on the equilibrium between U^{4+} and

Figure 32. Schematic of the Japanese chemical enrichment plant
a) Pump; b) Valve; c) Detector; d) Enrichment column; e) Regeneration reactors

UO_2^{2+} in aqueous solution in the presence of an ion-exchange material. In this environment, the preferred valence of ^{238}U is 4 and that of ^{235}U is 6. The ion-exchange material has no preference for either isotope, but it preferably adsorbs hexavalent uranium isotopes. So the overall effect is a slight increase in ^{235}U concentration. Since the enrichment factor is very small (1.001 to 1.0014), many stages in the sequence are necessary. The integration of many stages into a continuously operating column was achieved in the pilot plant with the development of the self-generation reaction (Addox reaction) between the deactivated redox agents. A regeneration of ca. 70 % is achieved in a semi-commercial plant. Figure 32 shows a schematic diagram of the plant.

In the column the zones are migrating continuously from top to bottom. In the adsorption zone the ion exchanger is loaded with ^{235}U. If the adsorption zone arrives at the valve, the adsorber is removed together with enriched uranium. The acceptor zone contains the depleted uranium. Uranium and regenerated ion exchanger material are introduced at the donor zone. The redox agents are regenerated in the addox boundary zone. Hydrogen and oxygen are fed in the area of the valve to complete regeneration of the redox agent.

In France, the equilibrium between U^{3+} and U^{4+} is utilized [53]. Separation occurs between an aqueous hydrochloric acid phase retaining trivalent ^{238}U and the phase of an organophosphorus compound, retaining $^{235}UCl_4$. The enrichment factor is ca. 1.025. This process also requires several thousand stages.

6.3.9.5. Laser Separation Process

Laser separation of isotopes is based on the fact that small differences exist between the absorption spectra of ^{235}U and ^{238}U. By using lasers of suitable wavelength, one isotope can be excited selectively. Two methods have been investigated, in one of which selective excitation is applied to uranium metal vapor, and in the other to gaseous UF_6. The first of these is known as the Atomic Vapor Laser Isotope Separation (AVLIS) process. Here, the selectively excited uranium atom is ionized and then separated electrostatically from the stream of metal vapor [54]. In the Molecular Laser Isotope Separation (MLIS) process, selectively excited UF_6 molecules dissociate into UF_5 and F. Fluorine must be bonded rapidly to suppress the reverse reaction. The UF_5 can then be separated from the stream of molecules [54]. Both processes require several stages despite the high separation factor. The AVLIS process is regarded as the

most promising because the sequence of stages can be put together without problems. However, in the MLIS process, UF_5 must be converted back to UF_6 after each stage [54]. For this reason, research in the United States was formerly concentrated on the AVLIS process.

Two possible methods of incorporating the AVLIS process into the series of operations to convert uranium ore into nuclear fuel are illustrated in Figure 33.

Figure 33. Example of incorporation of the AVLIS process into the chemical process chain of fuel element production

6.3.9.6. Plasma Processes

Two effects suitable for isotope separation are under investigation.

The first utilizes the fact that uranium plasmas rotating in magnetic fields achieve considerably higher rotational speeds than those produced by a centrifuge. Thus, uranium isotopes can be separated by gravity. The second effect utilizes the fact that in a homogeneous magnetic field the cyclotron frequency of the ions in the plasma depends only on magnetic field strength and ionic mass. Hence, the isotopes have different circulation paths in the cyclotron. Thus, isotopes are separated in a rotating plasma and collected separately by different collecting devices.

6.3.10. Production of UO_2 Pellets from UF_6

6.3.10.1. Conversion of UF_6 to UO_2

A schematic overview of industrially important processes for producing UO_2 pellets from UF_6 is given in Figure 34. These may be divided into wet and dry processes.

Wet Processes. Wet processes include the precipitation of ADU and AUC, as described in Section 6.3.5 for obtaining UO_2 from high-purity uranyl nitrate. The apparatus for converting UF_6 to UO_2 is illustrated in Figures 35 and 36. The difference from the processes described in Section 6.3.5 is that the starting material is UF_6. The following two reactions occur:

ADU process

$$2\,UF_6 + 2\,NH_3 + 7\,H_2O \rightarrow (NH_4)_2U_2O_7 + 12\,HF$$

AUC process

$$UF_6 + 5\,H_2O + 10\,NH_3 + 3\,CO_2 \rightarrow (NH_4)_4UO_2(CO_3)_3 + 6\,NH_4F$$

Subsequent conversion of ammonium diuranate or ammonium uranyl carbonate to UO_2 powder is carried out by methods similar to those already described. However, since conditions in the calcination stage significantly affect the properties of the powder for later finishing operations, properties are optimized by controlling those conditions.

Generally, the advantage of the ADU and AUC conversion routes is the possibility to process directly the UNH from recycling of wastes produced by fuel manufacturing.

Dry Processes. Reaction equations for dry processes are given below in simplified form:

$$UF_6 + 2\,H_2O \rightarrow UO_2F_2 + 4\,HF$$

$$UO_2F_2 + H_2 \rightarrow UO_2 + 2\,HF$$

However, these dry processes vary considerably with respect to processing details and design of the chemical reactors. In the older processes, up to four separate reaction chambers were required, whereas modern processes use one or at most two reaction chambers. A schematic diagram of the Direct Conversion (DC)

UF_6

Process step	Process				
	Wet processes		Dry processes		
	ADU	AUC	IDR	DC	GECO
UF_6 feed system	Vaporization of UF_6 from transport containers by controlled heating				
Precipitation or reaction	As ADU	As AUC	As UO_2	As UO_2 + UO_2F_2	As UO_2 + UO_2F_2
Recovery of first product	Filtration and drying		Filtration in sintered filter cartridges		
Conversion of first product into UO_2	Calcination ADU → UO_2	Calcination AUC → UO_2	↓	↓	Calcination F removal
Additions	U_3O_8, compaction auxiliaries	U_3O_8	U_3O_8, compaction auxiliaries		
Powder conditioners	Milling, compaction, granulation	↓	Milling, compaction, granulation		
Production of green pellets	Green pellets usually formed in mechanical rotary presses				
Sintering	Sintering in Mo boats under H_2 with controlled oxygen potential (H_2: H_2O ratio) at up to 1780°C to achieve good stoichiometry				
Finishing	Centerless grinding

process is given in Figure 37. Construction materials must be chosen very carefully because of the corrosive properties of the hot, gaseous hydrogen fluoride produced. However, satisfactory experience with this plant shows that reliable solutions to these problems have been achieved by materials technology.

6.3.10.2. Possible Future Developments in the Conversion of UF_6 to UO_2 Powder

Nowadays, both wet and dry processes are used worldwide to convert UF_6 to UO_2 powder for the production of nuclear fuel pellets for light-water reactors [55]. The combination of processes has

been optimized within the limits of process parameters to enable the pellets to be produced economically and in accordance with quality specifications. The standards established are applicable to all later production developments, especially the dry conversion processes.

Future Processes. In the production of UO_2 pellets, intermediate products in powder form can of course be avoided only by using *wet processes*. A possible approach is to use the sol – gel process [56, 57, 59], in which UF_6 is dissolved in aqueous uranyl nitrate solution and mixed with poly(vinyl alcohol). This solution is then sprayed into a second liquid with a very different surface tension, and ammonia is added. This causes hardening of the droplets to form particles, which are then washed in aqueous NH_3 solution to remove the undesired byproduct NH_4NO_3. A calcination process in air then decomposes the poly(vinyl alcohol) and the ammonium diuranate to UO_2. The solid particles obtained can then be compressed directly into pellets. The process is carried out in such a way that the UO_2 pellets are of similar quality and have similar properties to those produced by conventional processes.

However, analysis of this process shows that the many washing and purification steps and the considerable volume of materials used lead to a large volume of process and waste materials that must be cleaned and disposed of. Although very little dust is produced, the cost of cleaning and waste disposal is high. For this reason, the main interest in process development has now reverted to *dry processes* such as IDR, DC, and GECO, the industrial handling of dusts and aerosols having meanwhile been greatly improved.

All these processes convert UF_6 to UO_2 by the following reactions

$$UF_6 + 2\,H_2O\,(\text{steam}) \rightarrow UO_2F_2 + 4\,HF$$

$$UO_2F_2 + H_2 \rightarrow UO_2 + 2\,HF$$

These two reaction steps can be combined in one process as realized by the BNFL IDR process. Siemens prefers a two-step procedure. In a fluidized-bed reactor UO_2 is formed together with minor amounts of UO_2F_2 [58]. In a subsequent rotary kiln the $UO_2 - UO_2F_2$ mixture is converted to UO_2 which contains negligible impurities of fluorine. A slightly different approach is applied for conversion in the oxygen–hydrogen flame, which is also in use on a manufacturing scale (TVEL). Here the conversion of UF_6 to uranium oxide is performed already within a flame reactor with only small amounts of fluorides in the reaction product. A common feature of all processes is to provide a UO_2 powder with an acceptable sinterability and a low F content. Reducing the fluorine content requires a hydrogen treatment at higher temperature (500

Figure 38. AUC conversion – precipitation stage

– 800 °C), which results in an optimization of fluorine depletion and sinterability.

Chemicals and Residues in the AUC and DC Processes. Flows of materials in the *AUC process* are shown in Figures 38 and 39, in which the main product stream flows from left to right and the processing chemicals and residues flow from top to bottom. Figure 40 shows how the treatment (not presented in detail here) of processing chemicals and residues is integrated in such a way that it is compatible with the main process of $UF_6 \rightarrow UO_2$ conversion. Material flows are suitably interlinked to minimize consumption of raw materials and processing chemicals, and to recycle usable materials. At the same time, individual process steps must be op-

timized continuously to ensure compliance with steadily decreasing pollution limits.

Figure 41 shows the *DC process* in a diagram similar to that for the AUC process. The processing materials are steam, H_2, and N_2. In addition, HF is formed in amounts corresponding to the amounts of UF_6 treated. Gas streams passing from the reaction vessels are filtered several times to remove solids. After condensation of hydrogen fluoride, the gas is recycled as far as possible for use as a processing material. Residual gas is passed over $CaCO_3$ to remove HF completely, the traces of HF reacting to form CaF_2. The gas so obtained is flared off to remove H_2, and the waste-gas stream can be released from a stack since it contains only residual H_2 and H_2O. Fluorine introduced into the process in the form of UF_6 can be reused in the form of pure hydrofluoric acid. The small amounts of CaF_2 in $CaCO_3$ can be dumped without further treatment.

A comparison of the aqueous AUC process and the dry DC process shows that for the same product quality, the dry process has considerable advantages in the treatment of processing and waste materials. The DC process is consequently growing in importance, which shows how ongoing efforts to reduce pollution can also lead to process rationalization.

6.3.10.3. Pelletizing of UO_2 Powder

A process overview is given in Figure 34. The fuel pellets are generally fabricated by means of powder metallurgy processes: powder preparation–compaction–sintering. Some processes require preparation of the powder by compaction and granulation. When the AUC process is used, the UO_2 powder obtained can be compressed and sintered without any intermediate steps.

6.3.11. Production of Uranium Metal

The requirement for uranium metal is limited (Fig. 14). Only Magnox reactors for power generation require uranium metal as fuel (→ Nuclear Technology, Chap. 3.2.2.1). Uranium metal is also needed for the production of U – Zr, U – Zr hydride, uranium silicide, and uranium – aluminum alloys. If laser enrichment processes such as the AVLIS process attain industrial importance, the requirement for elementary uranium will increase. Uranium metal is produced from UF_6 by a two-stage reduction; the intermediate product is UF_4.

6.3.11.1. Reduction of UF_6 to UF_4

Two principal routes are used:

1) Reduction of UF_6 by H_2 in the gas phase
2) Reduction of UF_6 with chlorinated hydrocarbons (mainly unsaturated)

Reduction with Hydrogen. The throughput and degree of enrichment required are important considerations when selecting a process. Reduction of UF_6 by hydrogen in so-called hot-wall and cold-wall reactors was reported at the Geneva Conference of 1958 [60]. The reaction is exothermic:

$$UF_6 + H_2 \rightarrow UF_4 + 2\,HF \quad \Delta H = -281.7\,kJ/mol$$

The heat of this reaction is not sufficient to give quantitative conversion. The *hot-wall reactor* is therefore provided with external heating to give a wall temperature of 630 °C. The *cold-wall reactor* obtains its energy from the highly exothermic reaction of fluorine (mixed directly with UF_6) with excess hydrogen.

Reduction with Tetrachloroethylene. Reaction of UF_6 with tetrachloroethylene (C_2Cl_4) in a fluidized-bed furnace was developed by United Nuclear Corp. [61]:

$$UF_6 + Cl_2C{=}CCl_2 \rightarrow UF_4 + Cl_2FC{-}CFCl_2$$

The reaction temperature is 260 – 295 °C. Nitrogen is added to tetrachloroethylene to act as a carrier gas.

6.3.11.2. Reduction of UF_4 to Uranium Metal

Calcium, magnesium, and sodium are thermodynamically suitable agents for the reduction of UF_4 to uranium metal, but only calcium and magnesium are of practical importance – calcium for small batches because of its higher heat of reaction, and magnesium for larger quantities because it is the cheaper metal.

Figure 41. From UF_6 to UO_2 by the DC process
I = Gas stream is filtered and recycled to the process; II = Gas stream is recovered in the form of pure hydrofluoric acid; carrier gas is passed over $CaCO_3$ to remove residual HF, and H_2 is flared off.

Reduction with Calcium. The heat of reaction of reduction with calcium is very large:

$$UF_4 + 2\,Ca \rightarrow 2\,CaF_2 + U \quad \Delta H = -577.8\,kJ/mol$$

With a calcium excess of 15 % and adiabatic conditions during reduction, the temperature of the reaction mixture can rise to 1800 °C. This temperature is high enough to melt the slag formed (*mp* of CaF_2 1418 °C). Calcium granules (ca. 5 mm) are used, which must be very pure. High magnesium content may cause a violent reaction because the reaction temperature is higher than the boiling point of magnesium.

A mixture of UF_4 and calcium is charged into a steel reaction vessel whose inner walls are lined with high-purity CaF_2 (Fig. 42). This interior lining prevents the container material from reacting with molten uranium metal. Before reduction, the reaction apparatus is evacuated and filled with argon. The reaction mixture is then ignited electrically with an ignition pellet, and the reaction is complete after a few seconds. Molten uranium collects at the bottom of the reaction vessel and can be separated easily from the slag after the vessel is cooled. The yield of metal is ca. 98 – 99 % of theory.

Reduction with Magnesium. Uranium reduction on a larger scale (several hundred kilograms of metal) is usually carried out with the much cheaper magnesium. Also, since its relative atomic mass is only about half that of calcium, the amount of magnesium required is smaller. However, the price advantage is counterbalanced partly by the lower heat of reaction:

$$UF_4 + 2\,Mg \rightarrow U + 2\,MgF_2 \quad \Delta H = -349.6\,kJ/mol$$

which makes it necessary to heat the reaction mixture to ca. 600 °C. If the mixture is at room temperature when it is ignited, the melting point of uranium metal and of the MgF_2 slag (1263 °C) is not reached. By using an excess of 15 % magnesium, the temperature reached is only ca. 900 °C under adiabatic conditions.

Figure 42. Reactor for reduction of UF_4 with calcium
a) Pressure control valve; b) Heat protection shields; c) Circular water pipe for flange cooling; d) CaF_2 lining; e) Circular pipe for water jets

The interior walls of the reactor are often lined with dolomite. To obtain a good yield, the bulk density of UF_4 must be relatively high (>3 g/cm^3), giving good thermal conductivity. Briquetting the reaction mixture before loading it into the reactor vessel is therefore advantageous.

6.3.11.3. Production of Uranium Powder

Uranium powder can be obtained by reduction of UO_2, electrolysis of fused salts, or decomposition of uranium hydride.

Reduction of UO_2. Reduction of UO_2 with calcium or magnesium has not become widely established in industry because separation of the product from the slag is difficult. Also, the demand for uranium powder is limited.

Reduction with Calcium. The best reducing agent for UO_2 is calcium. A carefully prepared mixture of calcium granules and UO_2 is charged to a reactor whose walls are lined with CaO. The mixture is heated to 1200 °C under argon and kept at this temperature for at least 30 min. The temperature should reach the melting point of uranium (1132 °C) but should not cause CaO to melt. The uranium particles therefore become embedded in unmelted CaO. Excess calcium, which has low solubility in CaO, acts as a grain growth accelerator for the uranium.

After reaction, the mixture, which contains uranium and CaO together with excess calcium, is broken up and slurried with water. After careful addition of acetic acid (to buffer the solution at pH 5.5 by formation of calcium acetate), dilute nitric acid is added to leach out calcium. A temperature of 30 °C should not be exceeded in this leaching process because higher temperatures cause oxidation of the surface of the metal powder.

Reduction with Magnesium. The temperature during reduction with magnesium must be kept below 1270 °C; however, it should be above 1133 °C, which is higher than the *bp* of magnesium, so that large enough metal particles will be formed. The metal powder produced by reduction with magnesium is much finer than that obtained by reduction with calcium. Magnesium chloride is often added to the reaction mixture to act as a flux.

Electrolysis of Fused Salts. The electrowinning of metal powder is carried out in fused fluoride or chloride salts. KUF_5 or UF_4 is dissolved in a molten salt mixture of 80 % $CaCl_2$ and 20 % NaCl, and electrolyzed at 900 °C in a graphite crucible, which forms the anode. When withdrawing the cathode from the molten salt, appropriate precautions must be taken to prevent burning of powdered metal that adheres to it. After cooling, soluble chlorides can be removed from the metal by washing with water.

Decomposition of Uranium Hydride. Hydrogen reacts very readily with uranium metal, forming uranium hydride (UH_3). The optimum hydrogenation temperature is 220 °C. Because of the large density difference between the hydride (10.8 g/cm^3) and the metal (19.06 g/cm^3), the brittle hydride breaks down during the reaction into a fine pyrophoric powder. This is decomposed thermally at 310 °C with application of a vacuum to draw off hydrogen. The metal powder so obtained is strongly pyrophoric and can be handled only under an inert gas atmosphere.

7. Uranium Alloys

7.1. Classification

Light-water reactors, in which the nuclear fuel is UO_2, now dominate the power generation market, so uranium metal and uranium alloys have lost much of their industrial importance, although they are still used in materials testing reactors (MTRs), high-flux reactors, submarine reactors, and as shielding materials for radiation sources and irradiation equipment. Thus, only a small number of uranium alloys are still of interest. These can be classified as follows.

Metallurgical Mixtures of Mutually Insoluble Metal Phases. In this group of alloys, the components are mutually insoluble in the molten state (if solubilities in the part-per-million range are ignored) and form neither solid solutions nor mixed phases. Metals of technical importance include calcium and magnesium, which are used for reduction of UF_4. Reduction with calcium gives uranium metal containing <20 ppm Ca. This group also includes thorium, which has

Figure 43. U – C phase diagram [12]

a maximum solubility of 0.3 % in uranium at 900 °C.

Metals That Form Definite Intermetallic Phases with Uranium. These elements form definite intermetallic phases, but not solid solutions, with uranium. The only member of the group of current interest is carbon. Zirconium is of minor importance. The U – C phase diagram (Fig. 43) shows various uranium carbides that could be of importance as breeder reactor fuels. Properties and production of uranium carbides are described in Section 8.2. Even low carbon contents in uranium (<500 ppm) cause the metal to be hard and brittle. Machining of uranium containing >0.2 % C is practically impossible.

Metals That Form Solid Solutions. These metals are more or less mutually soluble but do not form solid intermetallic phases. They include chromium, silver, lead, molybdenum, niobium, titanium, tantalum, vanadium, and tungsten. Only molybdenum is of industrial importance since additions of 2 – 8 wt % molybdenum to uranium impart improved corrosion resistance. Uranium – molybdenum alloys can be used, therefore, as shielding materials for medical radiation equipment and in aircraft trimming weights, items that should not corrode in air.

Elements That Form Both Solid Solutions and Intermetallic Phases. These include aluminum, silicon, nitrogen, iron, gold, beryllium, manganese, nickel, and hydrogen. The most important metal in this group is aluminum because Al – U alloys can be used in special applications such as materials testing and high-flux reactors. The Al – U phase diagram is given in Figure 44. Work published in the late 1980s on the phase diagram gives slightly different results for the solidus – liquidus transition in medium-concentration regions [62].

7.2. Production of Important Alloys

U – Zr alloys are produced from the elements in metallic form. The best process is arc melting with consumable electrodes [63]. A homogeneous alloy is obtained by remelting the product two or three times by the same method. Final processing is by hot pressing, cutting, or machining.

U – Zr hydride is produced by hydrogenation of the U – Zr alloy at 300 – 900 °C. Since the absorption of hydrogen causes swelling, the process must occur slowly enough to ensure

Figure 44. U – Al phase diagram

that the stresses produced relax without causing cracking [63]. To be able to control the hydrogenation process by means of the H_2 partial pressure, detailed knowledge of the U – Zr – H system is necessary, including the phase diagram and the H_2 partial pressure of the hydrides ZrH_x [64]. Also, the level of impurities such as iron must be kept as low as possible because iron melts out locally as a low-melting U – Fe alloy during conversion of the U – Zr alloy into U – Zr hydride.

Uranium Silicides. For production of U_7Si, a mixture of uranium and silicon metal in the correct proportions is melted in a lined graphite crucible at 1640 – 1700 °C for ca. 10 min. The material is then cast in a graphite mold to form rods. The cast structure consists of ϵ-U_3Si_2 in a uranium matrix. The precipitated grains of ϵ-U_3Si_2 are surrounded by a layer of δ-U_3Si. The size and shape of the grains of ϵ-U_3Si_2 depend on cooling conditions. Hollow pellets can be prepared by casting in a suitable mold, although the material shrinks onto the core and the latter is then difficult to remove. A better method seems to be to drill a solid rod with a deep hole drilling machine.

To convert the structure of the solid into a δ-U_3Si phase that is as homogeneous as possible, it is annealed at 800 – 900 °C. The transformation is diffusion controlled and depends strongly on the form of the primary ϵ-U_3Si_2 precipitate in the cast structure. Optimum homogenization condition involves annealing at 800 – 820 °C for 100 h [65].

U – Al Alloys. Aluminum alloys containing 13 – 24 % uranium are used in the production of fuel elements for materials testing reactors and high-flux reactors, or the compound UAl_3 to obtain higher uranium contents. Whereas the alloy can be melted and cast, production of UAl_3 leads to brittle button-like formations. These can be pulverized easily, and the powder is then pressed and sintered to form the fuel rod.

8. Uranium Compounds

8.1. Halides

The most important halides (see Table 10) are the fluorides; polymers such as U_4F_{17} and U_5F_{22} are not included in this table because they have little technical importance.

Table 10. Halogen compounds of uranium (excluding polymeric compounds)

		Structure
Fluorides	UF_3	hexagonal, LaF_3 type
	UF_4	triclinic (pseudomonoclinic), isomorphous with ThF_4
	U_2F_9	cubic
	α-UF_5	tetragonal, chain structure
	β-UF_5	tetragonal, three-dimensional lattice
	UF_6	rhombic, molecular lattice
Chlorides	UCl_3	hexagonal, $La(OH)_3$ type
	UCl_4	tetragonal
	UCl_6	hexagonal, molecular lattice
Bromides and iodides	UBr_3	hexagonal, $La(OH)_3$ type
	UI_3	rhombic, LaI_3 type

8.1.1. Trivalent Halides

In general, trivalent halides may be prepared by reduction of the tetravalent compounds with hydrogen, e.g., [66]:

$$2\,UF_4 + H_2 \rightarrow 2\,UF_3 + 2\,HF$$

At 950 °C all of the UF_4 does not react; above 1080 °C, disproportionation of UF_3 into UF_4 and uranium occurs. Preparation of chlorides, bromides, and iodides involves similar problems.

Uranium trifluoride, UF_3, forms red-violet crystals. It is stable to moist air at room temperature, but is converted to oxide fluorides on heating and is oxidized to U_3O_8 above 900 °C. It is insoluble in cold water but is slowly oxidized to UF_4. In boiling water, further oxidization to uranyl fluoride occurs.

Uranium trichloride, UCl_3, forms dark red, very hygroscopic needles, *mp* 842 °C. In aqueous HCl solution, rapid transformation into a tetravalent green compound occurs, with liberation of hydrogen according to:

$$2\,UCl_3 + 2\,HCl \rightarrow 2\,UCl_4 + H_2$$

Uranium Tribromide and Triiodide. Uranium tribromide, UBr_3, *mp* 730 °C, and uranium triiodide, UI_3, *mp* 506 °C, are formed similarly to UF_3, and are also soluble in water.

8.1.2. Uranium Tetrahalides

Uranium tetrafluoride is a very important intermediate in the production of UF_6 for enrichment plants (see Section 6.2.2) and for production of the metal. It is a highly polymeric green solid that melts at 1034 [67] to 1036 °C [68]. Gaseous UF_4 is monomeric. The stability of solid UF_4 is explained by its complex crystal lattice (α-ZrF_4 structure). However, oxidation occurs in a stream of oxygen at 700 – 850 °C:

$$2\,UF_4 + O_2 \rightarrow UF_6 + UO_2F_2$$

Uranium tetrafluoride is almost insoluble in water and is dissolved only by oxidizing acids and some concentrated acids.

Hydrated UF_4 can also be prepared by precipitation from U(IV) solutions with hydrofluoric acid. At room temperature, the very pale green $UF_4 \cdot 2.5\,H_2O$ [69] is formed, but at 80 – 100 °C the grass green compound $UF_4 \cdot 0.75\,H_2O$ is obtained. Both can be converted into anhydrous UF_4 by careful dehydration in a vacuum.

Other Halides. Uranium tetrachloride (*mp* 569 °C), UBr_4 (*mp* 518 °C), and UI_4 (*mp* 706 °C) can be produced by heating a mixture of uranium oxides and carbon in a stream of halogen. Uranium tetrachloride dissolves very readily in water, with evolution of heat; UBr_4 and UI_4 behave similarly.

8.1.3. Uranium Pentafluoride

The reaction of UF_4 with UF_6 produces UF_5, which is formed together with U_2F_9 and U_4F_{17} as an intermediate in the production of UF_6 (see Section 6.3.7). UF_5 is now also important as an intermediate product formed during uranium enrichment using lasers (see Section 6.3.9.5). Other pentahalides are known but are of only theoretical interest.

8.1.4. Uranium Hexafluoride

Many possible methods can be used to produce UF_6, the more important are listed below:

$$U + 3\,F_2 \rightarrow UF_6 \text{ (hazardousreaction)}$$

$$UF_4 + F_2 \rightarrow UF_6 \text{ (at } 340^\circ\text{C)}, 50\%\ F_2 \text{ excess}$$

$$UO_2 + 3\,F_2 \rightarrow UF_6 + O_2 \text{ (at } 500^\circ\text{C)}$$

$$UO_3 + 3\,F_2 \rightarrow UF_6 + \frac{3}{2}O_2 \text{ (at } 400^\circ\text{C)}$$

$$U_3O_8 + 17\,F_2 \rightarrow 3\,UF_6 + 8\,F_2O \text{ (at } 360^\circ\text{C)}$$

$$UC_2 + 7\,F_2 \rightarrow UF_6 + 2\,CF_4 \text{ (at } 350^\circ\text{C)}$$

$$UO_2 + 4\,HF \rightarrow UF_4 + 2\,H_2O \text{ (at } 550^\circ\text{C)}$$

$$UF_4 + F_2 \rightarrow UF_6$$

$$U + 2\,BrF_3 \rightarrow UF_6 + Br_2 \text{ (at } 50-125^\circ\text{C)}$$

The only industrial route is from pure UF_4. The phase diagram of UF_6 is shown in Figure 45. At normal pressure, UF_6 sublimes at 56.54 °C and melts only under a pressure of 1.517×10^5 Pa at 64.05 °C.

Figure 45. Phase diagram of UF_6 [70]

The critical constants for UF_6 are [70] T_c, 230.5 ± 0.2 °C; p_c, $45.50 \pm 0.50 \times 10^5$ Pa; ϱ_c, 1.375 g/m^3; V_c, 0.256 L/mol.

Solid UF_6 has similarities to white phosphorus, having a colorless to yellowish appearance and being easily cut into pieces. However, in contrast to phosphorus, it reacts rapidly with moisture, hydrolyzing even in moist air to form the bluish compound UO_2F_2, which resembles cigarette smoke:

$$UF_6 + 2\,H_2O \rightarrow UO_2F_2 + 4\,HF$$

This fine bluish smoke enables the smallest UF_6 leak in pipework to be detected immediately. At increased temperatures, UF_6 gas reacts violently or explosively with organic substances, but metal and glass are not attacked in the absence of moisture. Comprehensive data on UF_6 can be found in [70].

8.2. Carbides

The three carbides UC, U_2C_3, and UC_2 appear in the U – C phase diagram (Fig. 43) [71]. Both UC and UC_2 are stable up to their melting points; U_2C_3 is an intermediate phase that disproportionates above 1800 °C into UC and UC_2 [72]. The carbide UC_2 is unstable below 1275 –1500 °C, disproportionating to form U_2C_3 and carbon [73]. Above 1800 °C, UC_2 has the composition U/C = 1.86 ± 0.02 (atomic ratio) and a cubic structure, whereas a tetragonal form exists between 1600 and 1800 °C with composition U/C = 1.96 ± 0.04. Various temperatures are quoted for the melting point. According to [74], the *mp* of UC is ca. 2350 °C, and that of UC_2 with the composition U/C = 1.9 is 2475 °C.

The carbides react very vigorously with water and are therefore not used in water-cooled nuclear reactors because secondary damage could occur in the event of a defective fuel rod. However, they can be used as nuclear fuel if cooling is by gas or sodium, two generations of reactors that could be important in the future. Carbide fuels are therefore not yet available on the market except for testing purposes. In experimental fuel elements, UC is used mainly in the form of pellets, rods, or coated particles.

Uranium carbide is produced by three main methods: (1) reaction of uranium metal with carbon; (2) reaction of uranium metal with alkanes; and (3) reaction of uranium oxides with carbon.

Reaction of Uranium Metal with Carbon. Stoichiometric UC is obtained when a mixture of uranium powder with carbon is compressed at 800 – 1000 °C [75]. The material so produced has a density of 98 % of the theoretical value and a Vickers hardness of 700 kg/mm^2, a figure normally only obtainable with UC sintered at 2000 °C. A somewhat lower-density UC is formed by compressing uranium powder with carbon at 700 – 800 °C and then sintering the pellets at 1100 °C [76].

Very pure and dense UC is obtained by arc melting of uranium and carbon under vacuum or argon. This method gives densities of 98 – 99.5 % of theory [77].

Reaction of Uranium Metal with Alkanes. Very fine uranium powder (produced by decomposition of uranium hydride) is reacted with methane at 600 – 900 °C to give very pure and dense UC [78]. Reaction times are 0.5 – 2 h. Propane has also been used successfully.

Reaction of Uranium Oxides with Carbon. This is the only reaction of industrial importance. The following reactions can occur:

$$U_3O_8 + 11\,C \rightarrow 3\,UC + 8\,CO \quad \text{(at 1800 °C)}$$
$$U_3O_8 + 14\,C \rightarrow 3\,UC_2 + 8\,CO \quad \text{(at 2400 °C)}$$
$$UO_2 + 3\,C \rightarrow UC + 2\,CO \quad \text{(at 1800 – 1900 °C)}$$

Nuclear fuels are produced by this method in a vacuum furnace or under a protective gas since UC is pyrophoric.

Production of UC Fuel Rods. Uranium carbide rods are produced by melting UC at ca. 2500 °C and casting in rod-shaped molds [79]. Of the possible melting processes (i.e., electron beam melting, induction melting, and arc melting), only the last has been developed to an industrial scale. Induction melting is particularly unsuitable because reaction with the walls of the graphite crucible occurs, converting UC to UC_2.

The process of melting UC in an electric arc furnace is known as skull melting; a solid shell of UC forms between the water-cooled copper crucible and the melt, preventing molten UC from reacting with the metal crucible. This ensures the required purity of the nuclear fuel. To be able to cast the melt, tilting furnaces or centrifugal casting furnaces are used.

8.3. Nitrides

The nitrides UN, U_2N_3, and UN_2 are analogous to the carbides. The mononitride has a theoretical density of 14.32 g/cm^3 [80]. Under N_2 at normal pressure (100 kPa), UN decomposes at 2800 °C in a uranium-rich melt with liberation of N_2. If the N_2 pressure is reduced to 10 kPa, the decomposition temperature decreases to 2080 °C. Above 250 kPa, UN melts without decomposition [81]. At nitrogen pressures above atmospheric and 1300 °C, U_2N_3 disproportionates into UN + UN_2 with a 13 % decrease in volume [82].

The *mononitride* is produced by three main methods:

1) Reaction of uranium metal with nitrogen
2) Reaction of UH_3 with nitrogen
3) Reaction of uranium oxide with carbon and nitrogen

The equations for these reactions are as follows [83]:

$$1)\ 2U + 3/2\,N_2 \xrightarrow{850\ °C} U_2N_3 \xrightarrow[\text{Vacuum}]{1300\ °C} 2UN + 1/2\,N_2$$

$$2)\ U + 1.5\,H_2 \xrightarrow{250\ °C} UH_3 \xrightarrow[+N_2]{800\ °C}$$
$$U_2N_3 \xrightarrow[\text{Vacuum}]{1300\ °C} 2UN + 1/2N$$

$$U + NH_3 \xrightarrow{300\ °C} UH_3 \xrightarrow[+N_2]{800\ °C}$$
$$U_2N_3 \xrightarrow[\text{Vacuum}]{1300\ °C} 2UN + 1/2N$$

$$3)\ 2UO_2 + 4C + N_2 \xrightarrow[1850\ °C]{1400-} 2UN + 4CO$$

If method 3 is used, the nitride always contains some carbon and oxygen [83].

The nitrides have not yet become important nuclear fuels for power reactors, but the properties of uranium nitrides have been investigated again in detail with the aim of using them as nuclear fuels for special reactors (e.g., in space applications) [84 – 87].

8.4. Oxides

The following oxides of uranium are known:

1) Uranium monoxide, UO, discovered by X-rays, of no industrial importance
2) Uranium dioxide, UO_2, an important reactor fuel
3) $UO_{2.3}$, stable only above 500 °C, tetragonal crystal structure
4) $UO_{2.33}$ – U_3O_7, tetragonal crystal structure
5) U_4O_9, formed as an intermediate from UO_2 at high temperature
6) U_2O_5, monoclinic crystal lattice, red-brown
7) U_3O_8, stable in all temperature regions ($U_2O_5 \cdot UO_3$), black
8) UO_3, stable up to ca. 300 °C, orange
9) Uranium peroxide, UO_4, light yellow

8.4.1. Uranium Dioxide

Production of the industrially important compound uranium dioxide is described in Section 6.3.5.3. Important physical properties are

Theoretical density	10.96 g/cm^3
Melting point	2860 ± 70.5 °C
Thermal conductivity	
at 500 °C	4.3 W m^{-1} K^{-1}
at 1100 °C	2.6 W m^{-1} K^{-1}
at 1650 °C	2.15 W m^{-1} K^{-1}
at 2200 °C	4.3 W m^{-1} K^{-1}
Linear coefficient of expansion (4–2800 °C)	1.1×10^{-5} K^{-1}
Specific heat capacity (32 – 315 °C)	237.4 J kg^{-1} K^{-1}
Electrical conductivity	
at 20 °C	5.6×10^{-3} Ω^{-1} m^{-1}
at 975 °C	3.0 Ω^{-1} m^{-1}
at 1790 °C	270 Ω^{-1} m^{-1}

The physical properties, such as thermal and electrical conductivities, melting point, etc., are strongly dependent on stoichiometry and possibly on impurities. At ambient temperature UO_2 is a p-type semiconductor. The crystal lattice of UO_2 is face-centered cubic of the CaF_2 type. Stoichiometric UO_2 powder is pyrophoric and is oxidized in air to intermediate products ($UO_{2.30}$ and $UO_{2.33}$) or to U_3O_8. A lattice parameter of 0.547 nm can be given for stoichiometric UO_2.

UO_2 powder with a large specific surface area is self-igniting. Therefore, handling of UO_2 powders with BET surfaces $\geq$2 m^2/g requires special precaution measures, e.g., surface oxidation in a controlled manner.

8.4.2. Uranium Trioxide

Normal decomposition at 300 °C of intermediate products obtained during uranium production always leads to orange-colored UO_3. At >400 °C, this begins to change into black U_3O_8. Uranium trioxide occurs in six forms:

- α-UO_3 is formed by careful decomposition of UO_4 at 450 – 500 °C [88].
- β-UO_3 is formed by slow decomposition of ammonium diuranate at 450 – 500 °C [89].
- γ-UO_3 is formed by slow decomposition of uranyl nitrate hexahydrate (e.g., 4 h at 550 °C) [90].
- δ-UO_3 is red and is formed by dehydration of $UO_3 \cdot H_2O$ in air at 375 °C [89].
- ϵ-UO_3 is brick red and is formed in a few minutes by oxidation of U_3O_8 with NO_2 at 350 °C [89].
- ζ-UO_3 is a brown powder produced by rapid decomposition of uranyl nitrate hexahydrate in the presence of 0.6 % sulfamic acid [91]. The existence of this compound is not yet certain.

Uranium trioxide can be an intermediate in the production of nuclear fuel, but it is not itself used.

8.4.3. Triuranium Octaoxide

The polymorphism of U_3O_8 is extremely complex, and the data are to some extent conflicting. A summary is given below:

At normal pressure, four modifications exist denoted by α, α', α'', and β. Of these, α and β are base-centered rhombic, α' is body-centered rhombic, and α'' is hexagonal. The α-forms are stable at low temperature (room temperature) and the β-form at high temperature (>730 °C). At 50 °C, the α-form changes to the α'-form [92]. The α-form changes to the β-form at high pressure or under shear forces at 1100 – 1500 °C in the presence of atmospheric oxygen [93]. However, β-U_3O_8 has a lower density and changes back to α-U_3O_8 at 50 °C. Therefore, the reported phase transitions depend on temperature, pressure, and redox reactions, which

cause changes in density. The interrelationships between the different phases are thus very complex.

Another U_3O_8 (or $UO_{2.67}$) phase has been described, which is formed only at high pressure at ca. 627 °C and has a face-centered cubic structure. The combination of pressure and shear stress is said to be important for formation of this phase [92]. Thus, cubic U_3O_8 is obtained from α-U_3O_8 by prolonged milling in a ball mill, conversion being almost complete after one week. Considerable amounts of water are taken up during milling. Therefore, to obtain a pure product, α-U_3O_8 is first milled for 72 h; the mixture of α-U_3O_8 and cubic U_3O_8 obtained is heated to 750 °C; this is then milled again for 24 h in the absence of moisture. After milling for another 30 h in contact with atmospheric oxygen, an amorphous variety of α-UO_3 is formed.

Of four other possible modifications, the existence of two is fairly well established: γ-U_3O_8 is said to be formed at 940 °C from β-U_3O_8 with a heat of transformation of 4.63 ± 0.06 kJ/mol [94]. At 120 °C, this changes back irreversibly to α-U_3O_8, the heat of transformation being 4.40 ± 0.21 kJ/mol. The δ-U_3O_8 modification is formed above 1050 °C [95]. It crystallizes in a rhombic structure with unit cell dimensions α = 0.670 nm, b = 1.246 nm, and c = 0.851 nm. The density is said to be 7.86 g/cm^3.

Oxygen is evolved when U_3O_8 melts, so the melting point cannot be determined; U_3O_8 vaporizes at 925 – 1525 °C with formation of mainly monomeric gaseous UO_3 [96].

The specific *magnetic susceptibility* of U_3O_8 does not obey the Curie law or the Curie – Weiss law; this indicates that U_3O_8 should be written as $U_2O_5 \cdot UO_3$. The *electrical conductivity* of $U_3O_{8\pm x}$ depends strongly on temperature and the O : U ratio, so a generally valid value cannot be given. However, at room temperature stoichiometric U_3O_8 exhibits an electrical conductivity of about 100 $\Omega^{-1}m^{-1}$. The oxide U_3O_8 is an *n*-type semiconductor. Conduction is thought to occur by electrons and also by holes. Because of its mixed oxide properties, electron transport from U(V) to U(VI) is assumed.

Chemical Properties. Triuranium octaoxide dissolves readily in oxidizing acids and is oxidized to the hexavalent state and hydrolyzed to uranyl salts [e.g., $UO_2(NO_3)_2$] in the aqueous phase. Uranyl chloride, UO_2Cl_2, is formed by passing HCl gas over U_3O_8 at 700 °C. Triuranium octaoxide is insoluble in water and is oxidized rapidly to UO_4 (uranium peroxide) by hydrogen peroxide; it is reduced by hydrogen or ammonia to UO_2 at >500 °C.

8.4.4. Peroxides

Of the uranium oxides containing a peroxide group, the existence of two is well established: UO_4 (crystallizing with two or four molecules of water) and U_2O_7 with or without water of crystallization.

The hydrate $UO_4 \cdot x\,H_2O$ can be precipitated easily from aqueous uranyl nitrate solutions at room temperature by addition of H_2O_2:

$$UO_2(NO_3)_2 + H_2O_2 + x\,H_2O \rightarrow UO_4 \cdot x\,H_2O + 2\,HNO_3$$

This precipitation easily can be performed continuously, and the precipitate can be dried to give a powder with good flow properties [97].

A UO_4 powder with good sintering properties is prepared from a solution of uranyl nitrate (90 – 120 g/L) in 0.5 mol/L HNO_3 to which ammonium nitrate (80 g/L) has been added. Precipitation at pH 1.5 and 40 °C occurs at a uranium : hydrogen peroxide ratio of 1 : 3. The UO_4 powder formed is a spheroidal to spherical agglomerate with a maximum particle size of 50 µm, although most particles are ca. 20 µm. Calcination of this powder gives a product with good sintering properties.

The hydrate $UO_4 \cdot x\,H_2O$ is pale yellow; $UO_4 \cdot 4\,H_2O$ is the main product at a precipitation temperature of <50 °C, $UO_4 \cdot 2\,H_2O$ at higher temperature. Careful dehydration in a vacuum at ca. 130 °C gives hydrated U_2O_7, which decomposes with liberation of oxygen above 150 °C.

The structure of $UO_4 \cdot x\,H_2O$ has not yet been established, but U_2O_7 probably has the following structure [98]:

This is a brick-red to orange hygroscopic substance [99].

8.5. Nitrates, Sulfates, and the Carbonato Complex

8.5.1. Nitrates

Uranium and its oxides dissolve in nitric acid to form uranyl nitrate:

$$UO_3 + 2\,HNO_3 \rightarrow UO_2(NO_3)_2 + H_2O$$

The hexahydrate crystallizes from weakly acidic supersaturated solutions, but tri- and dihydrates can be obtained at higher concentrations of HNO_3 (see Fig. 46). Upon evaporation of uranyl nitrate solutions to >450 g/L uranium, $UO_2(NO_3)_2 \cdot 6\,H_2O$ (*mp* 60 °C) crystallizes on cooling [100]. The uranium content of a solution boiling at 120 °C is ca. 1000 g/L. The trihydrate melts at 113 °C, and the dihydrate at 184 °C. No decomposition occurs up to this temperature, but denitration begins above 300 °C. The UO_3 so produced has a relatively high bulk density (3.5 – 4.3 g/cm^3) and, after reduction to UO_2, is not very suitable for the production of compressed and sintered pellets. The nitrate of U(IV), $U(NO_3)_4$, can be obtained by treatment of uranyl nitrate with reducing agents such as hydrazine, iron(II) formate, or SO_2, or by electrolytic reduction. Uranium(IV) nitrate is a green substance, in marked contrast to yellow $UO_2(NO_3)_2$. It oxidizes readily to U(VI) in air.

Figure 46. The $UO_2(NO_3)_2$ – HNO_3 – H_2O system

8.5.2. Sulfates

The sulfates of uranium are important because uranium ores are usually digested with sulfuric acid (see Section 6.3.1), which generally leads to the formation of uranyl sulfate, UO_2SO_4. The nature of the hydrates formed depends on the H_2SO_4 concentration (see Fig. 47). Sulfates of tetravalent uranium are more stable than nitrates. The following hydrates are known: $U(SO_4)_2 \cdot 8\,H_2O$, $U(SO_4)_2 \cdot 4\,H_2O$, $U(SO_4)_2 \cdot 9\,H_2O$, and $U(SO_4)_2 \cdot 2\,H_2O$.

Figure 47. The UO_2SO_4 – H_2SO_4 – H_2O system

8.5.3. Tricarbonatodioxouranate

Tricarbonatodioxouranate, $[UO_2(CO_3)_3]^{4-}$, is formed by alkaline digestion and in the AUC process. The ammonium salt of this anion (AUC) decomposes above 80 °C, liberating CO_2 and forming ammonium diuranate.

9. Safety

The normal safety precautions taken in the chemical industry when handling toxic, liquid, volatile, and gaseous substances must be observed also in the case of uranium, but in addition radiation protection and criticality safety must be included. These affect plant and equipment design and may necessitate the use of apparatus with dimensions not generally employed in chemical technology (see Section 9.3), but reflecting all considerations as regards chemical, nuclear, and radiological safety.

9.1. Radiation Shielding

Handling natural uranium that has not been irradiated does not present special problems.

Table 11. Maximum permitted uranium concentrations in the workplace (with figures for other toxic elements for comparison) [101]

	Outside atmosphere, μg/m^3	In the workplace	
		Inactive area, μg/cm^3	Active area *, μg/cm^3
Natural uranium	180	150	1500
Uranium with 5 % ^{235}U	42	35	350
Uranium with 10 % ^{235}U	24	20	200
HF	2000		
Pb	200		
Be	2.0		
^{239}Pu	0.000032	0.00017	0.0017

* Workplace where radioactive materials are processed.

The danger of unacceptable emission of radiation is generally small; nevertheless, all processes are generally emboxed. Special attention must be given to cleaning UF_6 cylinders because buildup of ^{234}Th, which is in equilibrium with ^{238}U, can occur. After evaporation of UF_6, the cylinder still contains residues in the form of uranium decay products. However, providing shielding against the intense β-radiation and bremsstrahlung emitted by these residues while they are being treated is not difficult.

In addition, the uranium content of the atmosphere and contamination of the workplace are measured and controlled to protect personnel from uptake of or contamination by uranium. If legal limits are exceeded, respiratory protection must be provided. Workers must also be examined with a lung monitor at regular intervals, and the uranium content of urine must be determined. If uptake of uranium is suspected, whole-body measurements must be carried out.

Maximum permitted uranium concentrations in air at the workplace and in the form of surface contamination are given in Table 11.

9.2. Safety Against Uncontrolled Criticality

Criticality safety includes all technical and organizational measures taken to prevent an uncontrolled chain reaction. Uranium with its natural isotopic composition becomes critical only under special reactor conditions. This means that a spontaneous chain reaction under the conditions of uranium processing is impossible. However, in contrast to uranium with a natural isotopic composition, enriched uranium can have a critical configuration under considerably simpler circumstances (e.g., during manufacture or storage of fuel elements). The critical mass depends mainly on the degree of enrichment of ^{235}U, the composition of the material, and the moderating effect of the geometrical configuration.

In the Federal Republic of Germany, for example, plants for processing nuclear fuels can, therefore, be operated only if they are licensed under § 7 of the Atomic Energy Law, which specifies essential criteria for the nuclear safety of personnel and of the environment. Similar regulations apply in other countries.

In older plants, the observance of limit values was ensured mainly by measures under the control of plant personnel, but in newer plants this has been superseded by automatic control and is largely independent of human error. Exact and in licensing approved and validated computer codes enable a reduction of extra safety margins, so that larger vessels can be used with the knowledge that they are geometrically safe with respect to permitted criticality dimensions. In addition, more precise calculation of neutron interactions between individual vessels can be carried out with these methods; hence, a space-saving arrangement of components is possible.

9.3. Geometrically Safe Vessels

The nuclear safety of a critically safe (k_{eff} <0.95) thickness of material is achieved by increasing the surface of a vessel, thereby increasing the loss of neutrons to the environment and preventing the neutron population necessary to reach a critical condition. The safe geometry is determined as follows:

A hypothetical optimum neutron reflector is assumed to be present at the vessel, whether or not this assumption corresponds to actual conditions. This assumed reflector reduces calculated neutron loss considerably, and, therefore, causes a calculated increase in activity exceeding that of the actual arrangement. The smallest dimensions of the vessel in which a self-sustaining chain reaction can occur are found, based on the combined effects of concentration of fissile material, degree of moderation, and neutron loss by leakage by using this conservative method of calculation. From these conservatively smallest critical dimensions for ideally reflected uranium – water systems, the largest safe subcritical dimensions for $k_{\mathrm{eff}} = 0.95$ can be deduced, including safety factors (Table 12). Safe maximum amounts of uranium under all circumstances are listed in columns 2 and 3 of Table 12. The geometric dimensions in columns 4 – 6 apply to any amounts of uranium, provided $\varrho_{\mathrm{u}} < 3.5$ g/cm^3.

9.4. Apparatus with Heterogeneous Neutron Absorbers

The dimensions of safe vessels are often too small to allow desired throughputs to be achieved. In these cases, considerable benefit can be obtained by incorporating heterogeneous neutron absorbers (nuclear poisons), such as boron carbide or cadmium, into the equipment. Their effect is very dependent on the spatial arrangement of the no-absorption or intermediate vessel walls. For example, fluidized-bed furnaces are provided with a nuclear poison consisting of a central boron carbide rod with double cladding, and rotary UO_2 mixers with a surface covering or cladding consisting of securely attached cadmium sheets. This ensures nuclear safety even if water penetrates the fluidized bed or rotary mixer (accident safety).

9.5. Neutron Interactions in the UO_2 Fabrication Plant

A nuclear fuel production plant contains many individual processing stations. Therefore, demonstrating that these will remain subcritical as individual units is not sufficient. Equally important is ensuring that no increase in criticality is caused by interactions of the systems, plant, and equipment due to the way in which they are arranged. The entire layout of processing and storage operations must therefore be in the form of subcritical geometry.

9.6. Transportation

Plants for ore extraction, processing, and concentration are usually geographically remote from those for fuel assembly production; thus, uranium and its compounds must be transported between these plants. Since the materials being transported are often fissile and radioactive, special precautions must be taken and rules observed. For this reason, the IAEA has issued *guidelines* that are updated continuously according to the latest knowledge (Regulations for the Safe Transport of Radioactive Materials, IAEA, Vienna), in which national safety regulations are also considered. In its "Safety Series" of publications, the IAEA includes *recommendations* for methods of transporting radioactive materials, taking international and national regulations into account.

Since shipments often cross international boundaries, international harmonization of rules and licensing procedures is necessary. This is controlled under the UNO umbrella (→ Transport, Handling, and Storage, Chap. 5.1) [102]. The aim of the recommendations, guidelines, and regulations is to protect the general public, transport operatives, and private property from both the direct and the delayed effects of radiation during transportation [102].

This protection is secured by:

1) Restriction of the nature and activity of the radioactive material, which must be transported only in packaging of a specified type
2) Specification of design criteria for each type of packaging
3) Rules for handling and storage during transportation

The regulations are intended to prevent the release and uptake of radioactive materials into the human organism, to protect against radiation emitted by the materials being transported, and

Table 12. Safe masses and geometries for uranium salts and solutions as a function of degree of enrichment for a total density of <3.5 g/m^3

Degree of enrichment, % ^{235}U	Mass of ^{235}U max., kg	Total mass of U max., kg	Safe volume, L	Safe cylinder diameter, cm	Safe thickness of material, cm
100	0.350	0.35	4.4	12.70	3.81
75	0.360	0.46	5.0	13.21	4.06
50	0.390	0.76	6.0	14.48	4.83
40	0.410	1.025	6.7	15.24	5.08
30	0.440	1.467	7.7	16.00	5.59
20	0.480	2.4	9.5	17.53	6.86
15	0.520	3.467	11.0	18.80	7.87
12	0.583	4.858	12.5	19.81	8.64
10	0.600	6.0	14.0	20.83	9.14
8.0	0.6650	8.125	16.0	22.10	9.91
6.0	0.710	11.833	20.5	24.38	11.43
5.0	0.800	16.0	27.0	26.04	12.70
4.0	0.930	23.25	33.8	28.45	13.97
3.5	1.04	29.714	40.0	30.48	15.24
3.0	1.20	40.0	49.2	32.51	16.51
2.5	1.47	58.8	64.6	35.56	18.03
2.0	2.0	100.0	95.1	40.64	22.10
1.75	2.56	146.286	126	44.70	24.38

to ensure that unforeseen criticality events do not occur.

These aims are achieved in practice by:

1) Containment of the material being transported, the design and sturdiness of the packaging depending on the activity and nature of this material
2) Limitation of the maximum dose level at the outer surface of the item being transported, by taking account of the contents of the package and storage techniques used in the transport system
3) Protection of the transport container from external effects of an accident, again by taking into account the nature and activity of the material being transported
4) Prevention of a criticality event by very restrictive assumptions with respect to the items being transported and the conditions that could arise from an accident

Experience with the transport of radioactive goods has justified the practices used internationally. In industrialized Western countries, no case of injury or death has resulted due to the release of radioactive materials in a transportation accident. This is supported by data from the following countries:

United States: A detailed study of 811 reported incidents between 1971 and 1981

United Kingdom: A study of 330 000 shipments of radioisotopes

Federal Republic of Germany: A study of shipments up to 1984 [103]

The positions are underlined when assessing the *Mont-Louis* incident. In August 1984, the freighter *Mont Louis*, with a cargo of 350 t UF_6, sank in 15 m water. Within 40 days, all of the containers were recovered undamaged from the wreck without any release of radioactivity.

Abbreviations:

CRH, %	critical relative humidity
ΔH_S, kJ/mol	integral heat of solution
m, mol/kg	urea molality, moles of urea per kilogram of water
$P^{O}_{(s)H^2}$, Pa	water vapor pressure of a saturated urea solution
P_v, Pa	vapor pressure

Urea [*57-13-6*], $CO(NH_2)_2$, M_r 60.056, plays an important role in many biological processes, among others in decomposition of proteins. The human body produces 20 – 30 g of urea per day.

In 1828, WÖHLER discovered [1] that urea can be produced from ammonia and cyanic acid in aqueous solution. Since then, research on the preparation of urea has continuously progressed. The starting point for the present industrial production of urea is the synthesis of BASAROFF [2], in which urea is obtained by dehydration of ammonium carbamate at increased temperature and pressure:

$$NH_2COONH_4 \rightleftarrows CO(NH_2)_2 + H_2O$$

In the beginning of this century, urea was produced on an industrial scale by hydration of cyanamide, which was obtained from calcium cyanamide:

$$CaCN_2 + H_2O + CO_2 \rightarrow CaCO_3 + CNNH_2$$

$$CNNH_2 + H_2O \rightarrow CO(NH_2)_2$$

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_333

After development of the NH_3 process (HABER and BOSCH, 1913, →Ammonia, Chap. 2. →Ammonia, Chap. 3. →Ammonia, Chap. 4.), the production of urea from NH_3 and CO_2, which are both formed in the NH_3 synthesis, developed rapidly:

$$2\,NH_3 + CO_2 \rightleftharpoons NH_2COONH_4$$

$$NH_2COONH_4 \rightleftharpoons CO(NH_2)_2 + H_2O$$

At present, urea is prepared on an industrial scale exclusively by reactions based on this reaction mechanism.

1. Physical Properties [3], [4]

Pure urea forms white, odorless, long, thin needles, but it can also appear in the form of rhomboid prisms. The crystal lattice is tetragonal – scalenohedral; the axis ratio $a : c$=1 : 0.833. The urea crystal is anisotropic (noncubic) and thus shows birefringence. At 20 °C the refractive indices are 1.484 and 1.602. Urea has an *mp* of 132.6 °C; its heat of fusion is 13.61 kJ/mol.

Physical properties of the melt at 135 °C follow:

ϱ	1247 kg/m^3
Molecular volume	48.16 m^3/kmol
η	3.018 mPa · s
Kinematic viscosity	2.42×10^{-6} m^2/s
Molar heat capacity, C_p	135.2 J mol^{-1} K^{-1}
Specific heat capacity, c_p	2.25 kJ kg^{-1} K^{-1}
Surface tension	66.3×10^{-3} N/m

In the temperature range 133 – 150 °C, density and dynamic viscosity of a urea melt can be calculated as follows:

$$r = 1638.5 - 0.96T$$

$$\ln\eta = 6700/T - 15.311$$

The density of the solid phase at 20 °C is 1335 kg/m^3; the temperature dependence of the density is given by 0.208 kg m^{-3} K^{-1}.

At 240 – 400 K, the molar heat capacity of the solid phase is [5]

$$C_p = 38.43 + 4.98 \times 10^{-2}T + 7.05 \times 10^{-4}T^2 - 8.61 \times 10^{-7}T^3$$

The vapor pressure of the solid phase between 56 and 130 °C [6] can be calculated from

$$\ln P_v = 32.472 - 11\,755/T$$

Hygroscopicity. The water vapor pressure of a saturated solution of urea in water $P^{O}_{(s)H^2}$ in the temperature range 10 – 80 °C is given by the relation [7]

$$\ln P_{(s)H_2O} = 175.766 - 11\,552/T - 22.679 \ln T$$

By starting from the vapor pressure of pure water $P^{O}_{H^2}$, the critical relative humidity (CRH) then can be calculated as

$$\mathrm{CRH} = \left(P_{(s)H_2O}/P_{H_2O}\right) 100$$

The CRH is a threshold value, above which urea starts absorbing moisture from ambient air. It shows the following dependence on temperature:

25 °C	76.5 %
30 °C	74.3 %
40 °C	69.2 %

At 25 °C, in the range of 0 – 20 mol of urea per kilogram of water, the integral heat of solution of urea crystals in water ΔH_s as a function of molality m is given by [8]:

$$\Delta H_s = 15.351 - 0.3523m + 2.327 \cdot 10^{-2}m^2 - 1.0106 \cdot 10^{-3}m^3 + 1.8853 \cdot 10^{-5}m^4$$

Urea forms a eutectic mixture with 67.5 wt % of water with a eutectic point at −11.5 °C.

The solubility of urea in a number of solvents, as a function of temperature is summarized in Table 1 [9], [10].

2. Chemical Properties

Upon *heating*, urea decomposes primarily to ammonia and isocyanic acid. As a result, the gas phase above a urea solution contains a considerable amount of HNCO, if the isomerization reaction in the liquid phase

$$CO(NH_2)_2 \rightleftharpoons NH_4NCO \rightleftharpoons NH_3 + HNCO$$

Table 1. Solubility of urea in various solvents (solubility in wt % of urea)

	Temperature, °C					
Solvent	0	20	40	60	80	100
Water	39.5	51.8	62.3	71.7	80.2	88.1
Ammonia	34.9	48.6	67.2	78.7	84.5	90.4
Methanol	13.0	18.0	26.1	38.6		
Ethanol	2.5	5.1	8.5	13.1		

has come to equilibrium [11]. In dilute aqueous solution, the HNCO formed hydrolyzes mainly to NH_3 and CO_2. In a more concentrated solution or in a urea melt, the isocyanic acid reacts further with urea, at relatively low temperature, to form biuret ($NH_2-CO-NH-CO-NH_2$), triuret ($NH_2-CO-NH-CO-NH-CO-NH_2$), and cyanuric acid $(HNCO)_3$ [12]. At higher temperature, guanidine $[CNH(NH_2)_2]$, ammelide $[C_3N_3(OH)_2NH_2]$, ammeline $[C_3N_3OH(NH_2)_2]$, and melamine $[C_3N_3(NH_2)_3]$ are also formed [13], [14].

Melamine can also be produced from urea by a catalytic reaction in the gas phase. To this end, urea is decomposed into NH_3 and HNCO at low pressure, and subsequently transformed catalytically to melamine (→Melamine and Guanamines, Chap. 4.).

Urea reacts with NO_x, both in the gas phase at 800 – 1150 °C and in the liquid phase at lower temperature, to form N_2, CO_2, and H_2O. This reaction is used industrially for the removal of NO_x from combustion gases [15], [16].

Reactions with Formaldehyde. Under *acid conditions*, urea reacts with formaldehyde to form among others, methyleneurea, as well as dimethylene-, trimethylene-, tetramethylene-, and polymethyleneureas. These products are used as slow-release fertilizer under the generic name ureaform [17] (→Fertilizers, Chap. 4.4.2.1.). The reaction scheme for the formation of methyleneurea is given below:

Methyleneurea reacts with additional molecules of formaldehyde to yield dimethyleneurea and other homologous products.

The reactions of urea with formaldehyde under *basic conditions* are used widely for the production of synthetic resins (→Amino Resins, Chap. 7.1.). As a first step, methylolurea instead of methyleneurea is formed:

This product subsequently reacts with formaldehyde to dimethylol urea, $CO(NHCH_2OH)_2$, and further polymerization products. Since urea is also the raw material for the production of melamine, from which melamine – formaldehyde resins are produced, it is the most important building block in the production of amino resins.

When urea is applied as fertilizer to soil, it *hydrolyzes* in the presence of the enzyme urease to NH_3 and CO_2, after which NH_3 is bacteriologically converted into nitrate and, as such, absorbed by crops [17].

3. Production

3.1. Principles

3.1.1. Chemical Equilibrium

In all commercial processes, urea is produced by reacting ammonia and carbon dioxide at elevated temperature and pressure according to the Basaroff reactions:

$$2\,NH_3\,(l) + CO_2\,(l) \rightleftharpoons NH_2COONH_4$$
$$\Delta H = -\,117\,\text{kJ/mol} \qquad (1)$$

$$NH_2COONH_4 \rightleftharpoons NH_2CONH_2 + H_2O$$
$$\Delta H = +\,15.5\,\text{kJ/mol} \qquad (2)$$

A schematic of the overall process and the physical and chemical equilibria involved is shown in Figure 1. In the first reaction, carbon dioxide and ammonia are converted to ammonium carbamate; the reaction is fast and exothermic. In the second rection, which is slow and endothermic, ammonium carbamate dehydrates to produce urea and water. Since more heat is produced in the first reaction than consumed in the second, the overall reaction is exothermic.

Figure 1. Physical and chemical equilibria in urea production

Processes differ mainly in the conditions (composition, temperature, and pressure) at which these reactions are carried out. Traditionally, the composition of the liquid phase in the reaction zone is expressed by two molar ratios: usually, the molar $NH_3 : CO_2$ and the molar $H_2O : CO_2$ ratios. Both reflect the composition of the so-called initial mixture [i.e., the hypothetical mixture consisting only of NH_3, CO_2, and H_2O if both Reactions (1) and (2) are shifted completely to the left].

First attempts to describe the chemical equilibrium of Reactions (1) and (2) were made by Frejacques [19]. Later descriptions of the chemical equilibria can be divided into regression analyses of measurements [20], [21] and thermodynamically consistent analyses of the equilibria [20], [22]. As far as the most important consequences of these equilibria on urea process design are concerned, the methods correspond closely to each other: The achievable conversion per pass, dictated by the chemical equilibrium as a function of temperature, goes through a maximum (Figs. 2 and 3). This effect is usually attributed to the fact that the ammonium carbamate concentration as a function of temperature goes through a maximum. This maximum in the ammonium carbamate concentration can be explained, at least qualitatively, by the respective heat effects of Reactions (1) and (2). However, this mechanism cannot explain the observed conversion maximum fully and quantitatively; other contributing mechanisms have been suggested [23].

Figure 2. Carbon dioxide conversion at chemical equilibrium as a function of temperature
$NH_3 : CO_2$ ratio = 3.5 mol/mol (initial mixture); $H_2O : CO_2$ ratio = 0.25 mol/mol (initial mixture)

Figure 3. Ammonia conversion at chemical equilibrium as a function of temperature
$NH_3 : CO_2$ ratio = 3.5 mol/mol (initial mixture); $H_2O : CO_2$ ratio = 0.25 mol/mol (initial mixture)

The influence of the composition of the initial mixture on the chemical equilibrium can be explained qualitatively by Reactions (1) and (2) and the law of mass action:

1) Increasing the $NH_3 : CO_2$ ratio (increasing the NH_3 concentration) increases CO_2 conversion, but reduces NH_3 conversion (Figs. 4 and 5).
2) Increasing the amount of water in the initial mixture (increasing the $H_2O : CO_2$ ratio) results in a decrease in both CO_2 and NH_3 conversion (Figs. 6 and 7).

In these cases, too, a full quantitative description cannot be derived simply from the law of mass action and Reactions (1) and (2). Other, not yet fully understood reaction mechanisms probably contribute to the chemical equilibria to a minor extent.

Figure 4. Carbon dioxide conversion at chemical equilibrium as a function of $NH_3 : CO_2$ ratio
$T = 190\,°C$; $H_2O : CO_2$ ratio = 0.25 mol/mol (initial mixture)

Figure 5. Ammonia conversion at chemical equilibrium as a function of $NH_3 : CO_2$ ratio
$T = 190\,°C$; $H_2O : CO_2$ ratio = 0.25 mol/mol (initial mixture)

Figure 6. Carbon dioxide conversion at chemical equilibrium as a function of $H_2O : CO_2$ ratio
$T = 190\,°C$; $NH_3 : CO_2$ ratio = 3.5 mol/mol (initial mixture)

Figure 7. Ammonia conversion at chemical equilibrium as a function of $H_2O : CO_2$ ratio
$T = 190\,°C$; $NH_3 : CO_2$ ratio = 3.5 mol/mol (initial mixture)

In Figures 2, 4, and 6, the conversion at chemical equilibrium is expressed as CO_2 conversion, that is, the amount of CO_2 in the initial mixture converted into urea (plus biuret), if no changes occur in overall NH_3, CO_2, and H_2O concentrations in the liquid phase. This way of representing the chemical equilibrium is consistent with the presentation usually found in the traditional urea literature. However, it is based on the arbitrary choice of CO_2 as the key component. Historically, this may be justified by the fact that in early urea processes, CO_2 conversion was more important than NH_3 conversion. For the present generation of stripping processes, however, giving a higher weight to CO_2 conversion is not justified. Comparing, e.g., Figs. 4 and 5,

shows that an arbitrary choice of one of the two feedstock components as yardstick to evaluate optimum reaction conversion can easily lead to faulty conclusions.

Figure 8. Urea yield in the liquid phase at chemical equilibrium as a function of temperature
$NH_3 : CO_2$ ratio = 3.5 mol/mol (initial mixture); H_2O: CO_2 ratio = 0.25 mol/mol (initial mixture)

Figure 9. Urea yield in the liquid phase at chemical equilibrium as a function of $H_2O : CO_2$ ratio
$T = 190\,°C$; $NH_3 : CO_2$ ratio = 3.5 mol/mol (initial mixture)

Ultimately, project economics (investment and consumptions) will dictate the choice of process parameters in the reaction section. Without going into such time- and place-dependent economic considerations, one can argue that the urea yield (i.e., the concentration of urea in the liquid phase) is a better tool for judging optimum process parameters than CO_2 or NH_3 conversion. Figure 8 illustrates that urea yield as a function of temperature also goes through a maximum; the location of this maximum is of course composition dependent. Figure 9 again shows the detrimental effect of excess water on urea yield; thus, one of the targets in designing a recycle system must be to minimize water recycle.

Figure 10 shows that the urea yield as a function of $NH_3 : CO_2$ ratio reaches a maximum somewhat above the stoichiometric ratio (2 : 1). This is one of the reasons that all commercial processes operate at $NH_3 : CO_2$ ratios above the stoichiometric ratio. Another important reason for this can be found from the physical phase equilibria in the $NH_3 - CO_2 - H_2O -$ urea system.

Figure 10. Urea yield in the liquid phase at chemical equilibrium as a function of $NH_3 : CO_2$ ratio
$T = 190\,°C$; $H_2O : CO_2$ ratio = 0.25 mol/mol (initial mixture)

3.1.2. Physical Phase Equilibria

In urea production, the phase behavior of the components under synthesis conditions is important. In all commercial processes, conditions are such that pressure and temperature are well above the critical conditions of the feedstocks ammonia and carbon dioxide; i.e., both components are in the supercritical state. The chemical interaction between NH_3 and CO_2 (mainly the formation of ammonium carbamate) results in a strongly azeotropic behavior of the "binary" system $NH_3 - CO_2$. An approach to the description of the phase equilibria if urea and water are added to the $NH_3 - CO_2$ system was given by Kaasenbrood and Chermin [24]. If

a less volatile solvent C (water) is added to an azeotropic system A – B ($NH_3 - CO_2$) at a pressure where both components A and B are supercritical, then the $T - X$ liquid and gas planes for the ternary system thus formed assume a special shape owing to the peculiar path described by the boiling points of the changing solutions (Fig. 11). Sections through the liquid plane for constant solvent content are analogous to the liquid line for the binary system. The liquid plane for the ternary systems appears as a ridge in the $T - X$ space. If the peak points of this ridge are linked up, the top ridge line is obtained. The points on this line do not have the same A : B ratio as the maximum for the binary azeotrope, because A and B are not soluble in solvent C to the same extent. The A : B ratio changes and the boiling point increases as the percentage of C increases.

Figure 11. Liquid – gas equilibrium in a ternary system with binary azeotrope at constant pressure
The system A – B forms a binary azeotrope; C is a solvent for both A and B. The pressure is such that both A and B are supercritical, whereas the pressure is below the critical pressure of C.

Analogous to the description of Figure 11, the equilibria in the $NH_3 - CO_2 - H_2O$ – urea system under urea synthesis conditions show a maximum in temperature at a given pressure as a function of $NH_3 : CO_2$ ratio. A full description of the phase equilibria in this system is even more complex than the aforementioned hypothetical A – B – C system, since the solid – liquid (S – L) and solid – gas (S – G) equilibria interfere with the liquid – gas (L – G) equilibria.

The strongly azeotropic behavior of the $NH_3 - CO_2$ system, and the associated temperature maximum (or pressure minimum) in the ternary and quaternary systems with water and urea, are of practical importance in the realization of commercial urea processes. Carbon dioxide is less soluble than ammonia in water and urea melts. As a result, the pressure gradient at constant temperature is much steeper on the CO_2-rich side of the top ridge line. Moreover, this difference in solubility also causes the pressure minimum (or temperature maximum) to shift toward higher $NH_3 : CO_2$ ratios as the amount of solvent (water and urea) increases. Practically, this means that in order to achieve relatively low pressures at a given temperature, the $NH_3 : CO_2$ ratio in all commercial processes is chosen well above the stoichiometric ratio (2 : 1). In some processes, this ratio is chosen on the pressure minimum (on the top ridge line, i.e., at a ratio of ca. 3 : 1), whereas in other processes an even greater excess of ammonia is used.

3.2. Challenges in Urea Production Process Design

Like any process design, a urea plant design has to fulfil a number of criteria. Most important items are product quality, feedstocks and utilities consumptions, environmental aspects, safety, reliability of operation and a low initial investment. Since the urea process already has half a century of commercial scale history, it will be clear that compromises between the aforementioned, partly conflicting, criteria are well established. Also resulting from the age of urea process design is the observation that a process can only be successful if acceptable and competing solutions to all of these criteria can be combined into one process design. Apart from applying straightforward normal engineering approaches,

the challenge of finding an optimum synergy between partly conflicting criteria, focuses in urea plant design essentially on a few peculiarities:

1) The thermodynamic limit on the conversion per pass through the urea reactor, combined with the azeotropic behavior of the $NH_3 - CO_2$ system, necessitates a cunning recycle system design.
2) The intermediate product ammonium carbamate is extremely corrosive. A proper combination of process conditions, construction materials, and equipment design is therefore essential.
3) The occurrence of two side reactions – hydrolysis of urea and biuret formation – must be considered.

3.2.1. Recycle of Nonconverted Ammonia and Carbon Dioxide

The description of the chemical equilibria in Section 3.1.1 indicates that the conversion of the feedstocks NH_3 and CO_2 to urea is limited. An important differentiator between processes is the way these nonconverted materials are handled.

Once-Through Processes. In the very first processes, nonconverted NH_3 was neutralized with acids (e.g., nitric acid) to produce ammonium salts (such as ammonium nitrate) as coproducts of urea production. In this way, a relatively simple urea process scheme was realized. The main disadvantages of the once-through processes are the large quantity of ammonium salt formed as coproduct and the limited amount of overall carbon dioxide conversion that can be achieved. A peculiar aspect of this historic development is a partial "revival" of these combined urea – ammonium nitrate production facilities (UAN plants, see Section 3.3.3).

Conventional Recycle Processes. Once-through processes were soon replaced by total-recycle processes, where essentially all of the nonconverted ammonia and carbon dioxide were recycled to the urea reactor. In the first generation of total-recycle processes, several licensors developed schemes in which the recirculation of nonconverted NH_3 and CO_2 was performed in two stages. Figure 12 is a typical flow sheet of these, now called conventional, processes. The first recirculation stage was operated at medium pressure (18 – 25 bar); the second, at low pressure (2 – 5 bar). The first recirculation stage comprises at least a decomposition heater (d), in which carbamate decomposes into gaseous NH_3 and CO_2, while excess NH_3 evaporates simultaneously. The off-gas from this first decomposition step was subjected to rectification (e), from which relatively pure NH_3 (at the top) and a bottom product consisting of an aqueous ammonium carbamate solution were obtained. Both products are reycled separately to the urea reactor (c). In these processes, all nonconverted CO_2 was recycled as an aqueous solution, whereas the main portion of nonconverted NH_3 was recycled without an associated water recycle. Because of the detrimental effect of water on reaction conversion (see Figs. 6, 7, and 9), achieving a minimum CO_2 recycle (and thus maximum CO_2 conversion per reaction pass) was much more important than achieving a low NH_3 recycle. All conventional processes therefore typically operate at high $NH_3 : CO_2$ ratios (4 – 5 mol/mol) to maximize CO_2 conversion per pass. Although some of these conventional processes, partly equipped with ingenious heat-exchanging networks, have survived until now (see Section 3.3.1), their importance decreased rapidly as the so-called stripping processes were developed.

Stripping Processes. In the 1960s, the Stamicarbon CO_2-stripping process was developed, followed later by other processes (see Section 3.3.2). Characteristic of these processes is that the major part of the recycle of both nonconverted NH_3 and nonconverted CO_2 occurs via the gas phase, such that none of these recycles is associated with a large water recycle to the synthesis zone. Another characteristic difference between conventional and stripping processes in terms of the recycle scheme, can be found in the way heat is supplied to the recirculation zones. The energy balance of the conventional processes is shown in Figure 13. In this first-generation urea process, the heat supplied to the urea synthesis solution was used only once; therefore, this type of process can be referred to as an $N = 1$ process. Such a process required about 1.8 t of steam per tonne of urea.

Figure 12. Typical flow sheet of a conventional urea plant

Figure 13. Conceptual diagram of the heat balance of a conventional urea process
Heat to each subsequent heater is supplied in the form of steam; the heat is used only once ($N = 1$).

Figure 14. Conceptual diagram of the heat balance of a stripping plant
Heat supplied to the first heater (the stripper) is recovered in the first condenser (high-pressure carbamate condenser) and subsequently used again in the low-pressure heaters (decomposers and water evaporators); the heat is effectively used twice ($N = 2$).

The energy balance of a stripping plant is shown in Figure 14. As in conventional plants, heat must be supplied to the urea synthesis solution to decompose unconverted carbamate and to evaporate excess ammonia and water. However, a distinct difference in the heat balance with respect to the conventional process is that only the heat in the first heater (the high-pressure stripper) is imported. This heat is recovered in a high-pressure carbamate condenser (unconverted ammonia and carbon dioxide are condensed to form ammonium carbamate) and reused in the low-pressure heaters. The heat supplied is effectively used twice; thus, the term $N = 2$ process is used. The average energy consumption of the stripping process is 0.8 – 1.0 t of steam per tonne of urea.

In the 1980s, some processes were described that aim at a greater reduction of energy consumption by a further application of this multiple effect to $N = 3$ (Fig. 15) [25–29]. As can be seen from Figures 14 and 15, the steam requirement for process heating is reduced in these types of processes. However, whether the total energy consumption for the process is also reduced is doubtful, if the full capabilities of a $N = 2$ type of process are exploited and if the total energy supply scheme, including the energy supply to the carbon dioxide compressor drive, are taken into consideration [30]. Moreover, it seems that the emphasis in urea technology now is shifting from low energy consumption toward other

factors, such as more durable construction materials, more modern process control systems, and simple process design [31].

Figure 15. Further heat integration of a stripping plant in conceptual form
Heat supplied to the first heater (the stripper) is effectively used three times ($N = 3$).

3.2.2. Corrosion [32]

Urea synthesis solutions are very corrosive. Generally, ammonium carbamate is considered the aggressive component. This follows from the observation that carbamate-containing product streams are corrosive whereas pure urea solutions are not. The corrosiveness of the synthesis solution has forced urea manufacturers to set very strict demands on the quality and composition of construction materials. Awareness of the important factors in material selection, equipment manufacture and inspection, technological design and proper operations of the plant, together with periodic inspections and nondestructive testing are the key factors for safe operation for many years.

Role of Oxygen Content. Since the liquid phase in urea synthesis behaves as an electrolyte, the corrosion it causes is of an electrochemical nature. Stainless steel in a corrosive medium owes its corrosion resistance to the presence of a protective oxide layer on the metal. As long as this layer is intact, the metal corrodes at a very low rate. Passive corrosion rates of austenitic urea-grade stainless steels are generally between <0.01 and (max.) 0.10 mm/a. Upon removal of the oxide layer, activation and, consequently, corrosion set in unless the medium contains sufficient oxygen or oxidation agent to build a new layer. Active corrosion rates can reach values of 50 mm/a. Stainless steel exposed to carbamate-containing solutions involved in urea synthesis can be kept in a passivated (noncorroding) state by a given quantity of oxygen. If the oxygen content drops below this limit, corrosion starts after some time – its onset depending on process conditions and the quality of the passive layer. Hence, introduction of oxygen and maintenance of a sufficiently high oxygen content in the various process streams are prerequisites to preventing corrosion of the equipment. Although some alternatives have been mentioned [33], [34], the use of oxygen to influence the redox potential has become common practice in urea manufacture ever since it was initially suggested [35], [36].

From the point of view of corrosion prevention, the condensation of $NH_3 - CO_2 - H_2O$ gas mixtures to carbamate solutions deserves great attention. This is necessary because – notwithstanding the presence of oxygen in the gas phase – an oxygen-deficient corrosive condensate is initially formed on condensation. In this condensate the oxygen is absorbed only slowly. This accounts for the severe corrosion sometimes observed in cold spots inside gas lines. The trouble can be remedied by adequate isolation and tracing of the lines.

When condensation constitutes an essential process step – for example, in high-pressure and low-pressure carbamate condensers – special technological measures must be taken. These measures can involve ensuring that an oxygen-rich liquid phase is introduced into the condenser, while appropriate liquid – gas distribution devices ensure that no dry spots exist on condensing surfaces.

Not only condensing but also stagnant conditions are dangerous, especially where narrow crevices are present, into which hardly any oxygen can penetrate and oxygen depletion may occur.

Role of Temperature and Other Process Parameters in Corrosion. *Temperature* is the most important technological factor in the behavior of the steels employed in urea synthesis. An increase in temperature increases active corrosion, but more important, above a critical temperature it causes spontaneous activation of passive steel. The higher-alloyed austenitic stain-

less steels (e.g., containing 25 wt % chromium, 22 wt % nickel, and 2 wt % molybdenum) appear to be much less sensitive to this critical temperature than 316 L types of steel.

Sometimes, the *NH_3 : CO_2 ratio* in synthesis solutions is also claimed to have an influence on the corrosion rate of steels under urea synthesis conditions. Experiments have showed that under practical conditions this influence is not measurable because the steel retains passivity. Spontaneous activation did not occur. Only with electrochemical activation could 316 L types of steel be activated at intermediate $NH_3 : CO_2$ ratios. At low and high ratios, 316 L stainless steel could not be activated. The higher-alloyed steel type 25 Cr 22 Ni 2 Mo showed stable passivity, irrespective of the $NH_3 : CO_2$ ratio, even when activated electrochemically. Of course, these results depend on the specific temperature and oxygen content during the experiments.

Material Selection. Corrosion resistance is not the only factor determining the choice of construction materials. Other factors such as mechanical properties, workability, and weldability, as well as economic considerations such as price, availability, and delivery time, also deserve attention.

Stainless steels that have found wide use are the austenitic grades AISI 316 L and 317 L. Like all Cr-containing stainless steels, AISI 316 L and 317 L are not resistant to the action of sulfides. Hence it is imperative in plants using the 316 L and 317 L grades in combination with CO_2 derived from sulfur-containing gas, to purify this gas or the CO_2 thoroughly.

In stripping processes, the process conditions in the high-pressure stripper are most severe with respect to corrosion.

In the *Stamicarbon CO_2-stripping process*, a higher-alloyed, but still fully austenitic stainless steel (25 Cr 22 Ni 2 Mo) was chosen as construction material for the stripper tubes. This choice ensures better corrosion resistance than 316 L or 317 L types of material but still maintains the advantages of workability, weldability, reparability, and the cheaper price of stainless steel-type materials.

In the *Snamprogetti stripping processes*, titanium usually is chosen for this critical application, although mechanically bonded bimetallic 25 Cr 22 Ni 2Mo – zirconium tubes have also been suggested to improve corrosion resistance [37], [38].

In the *ACES process*, duplex alloys (ferritic – austenitic) are used as construction material for the stripper tubes.

3.2.3. Side Reactions [39]

Three side reactions are of special importance in the design of urea production processes:

Hydrolysis of urea

$$CO(NH_2)_2 + H_2O \rightarrow NH_2COONH_4 \rightarrow 2\,NH_3 + CO_2 \quad (3)$$

Biuret formation from urea:

$$2\,CO(NH_2)_2 \rightarrow NH_2CONHCONH_2 + NH_3 \quad (4)$$

Formation of isocyanic acid from urea:

$$CO(NH_2)_2 \rightarrow NH_4NCO \rightarrow NH_3 + HNCO \quad (5)$$

All three side reactions have in common the decomposition of urea; thus, the extent to which they occur must be minimized.

The *hydrolysis reaction* (3) is nothing but the reverse of urea formation. Whereas this reaction approaches equilibrium in the reactor, in all downstream sections of the plant the NH_3 and CO_2 concentrations in urea-containing solutions are such that Reaction (3) is shifted to the right. The extent to which the reaction occurs is determined by temperature (high temperatures favor hydrolysis) and reaction kinetics; in practice, this means that retention times of urea-containing solutions at high temperatures must be minimized.

The *biuret reaction* (4) also approaches equilibrium in the urea reactor [20], [22]. The high NH_3 concentration in the reactor shifts Reaction (4) to the left, such that only a small amount of biuret is formed in the reactor. In downstream sections of the plant, NH_3 is removed from the urea solutions, thereby creating a driving force for biuret formation. The extent to which biuret is formed is determined by reaction kinetics; therefore, the practical measures to minimize biuret formation are the same as described above for the hydrolysis reaction.

Reaction (5) shows that formation of isocyanic acid from urea is also favored by low NH_3 concentrations. This reaction is especially

relevant in the evaporation section of the plant. Here, low pressures are applied, resulting in a transfer of NH_3 and HNCO into the gas phase and, consequently, low concentrations of these constituents in the liquid phase. Together with the relatively high temperatures in the evaporators, this shifts Reaction (5) to the right. The extent to which this reaction occurs is again determined by kinetics. The HNCO removed via the gas in the evaporators collects in the process condensate from the vacuum condensers, where low temperatures shift Reaction (5) to the left, again forming urea. As a result of this mechanism of chemical entrainment, attempts to minimize entrainment from evaporators with physical (liquid – gas) separation devices are destined to be unsuccessful.

3.3. Description of Processes

3.3.1. Conventional Processes

As explained in Section 3.2, conventional processes have generally been replaced by stripping processes. Only two conventional processes may still have some importance in the near future.

Urea Technologies Inc. (UTI) Heat Recycle Process (see Fig. 16). Ammonia (containing passivating air), recycled carbamate, and about 60 % of the feed CO_2 are charged to the top of an open-ended coil reactor (c) operating at 210 bar. Ammonium carbamate is formed within the coil, exits the coil at the bottom, and then flows up and around it–the exothermic heat of carbamate formation in the coil driving the endothermic dehydration of carbamate to urea outside the coil. The reactor is claimed to achieve a uniform temperature profile in this way. In the reactor, a relative high $NH_3 : CO_2$ ratio (4.2 : 1) is applied. The reactor effluent is depressurized and subcooled, and the flashed gases are released before the first decomposer (f). Gases leaving the first decomposer separator (g) are mixed with about 40 % of the feed carbon dioxide and partially condensed in the heat recovery section (i – k). The two combined gas streams are then further condensed and form the carbamate recycle flow. Urea as an 86 – 88 % solution is concentrated by evaporation (i) before granulation or prilling. The process is applied in eight small-scale and two medium-scale plants.

MTC (Mitsui Toatsu Corporation) Conventional Processes of Toyo Engineering Corporation. The conventional processes developed by Toyo Engineering Corporation (TEC) were successfully commercialized until the mid-1980s. The continuous evolution of these processes is reflected in their sequential nomenclature:

TR – A	Total-Recycle A Process
TR – B	Total-Recycle B Process
TR – C	Total-Recycle C Process
TR – CI	Total-Recycle C Improved Process
TR – D	Total-Recycle D Process

Partial-recycle versions of these processes were also realized. These TEC MTC conventional processes were applied in more then 70 plants. However, the licensor of these processes has announced a stripping process (the ACES process; see Section 3.3.2.3); this probably means the end of the TEC MTC conventional process line.

3.3.2. Stripping Processes

3.3.2.1. Stamicarbon CO_2-Stripping Process (Figs. 17 and 18)

The synthesis stage of the Stamicarbon process consists of a urea reactor (c), a stripper for unconverted reactants (d), a high-pressure carbamate condenser (e), and a high-pressure reactor off-gas scrubber (f). To realize maximum urea yield per pass through the reactor at the stipulated optimum pressure of 140 bar, an $NH_3 : CO_2$ molar ratio of 3 : 1 is applied. The greater part of the unconverted carbamate is decomposed in the stripper, where ammonia and carbon dioxide are stripped off. This stripping action is effected by countercurrent contact between the urea solution and fresh carbon dioxide at synthesis pressure. Low ammonia and carbon dioxide concentrations in the stripped urea solution are obtained, such that the recycle from the low-pressure recirculation stage (h, j) is minimized. These low concentrations of both ammonia and carbon dioxide in the stripper effluent can be obtained at relatively low temperatures of the urea solution because carbon dioxide is only sparingly soluble under such conditions.

Figure 18. Functional block diagram of the Stamicarbon CO_2-stripping urea process

Condensation of ammonia and carbon dioxide gases, leaving the stripper, occurs in the high-pressure carbamate condenser (e) at synthesis pressure. As a result, the heat liberated from ammonium carbamate formation is at a high temperature. This heat is used for the production of 4.5-bar steam for use in the urea plant itself. The condensation in the high-pressure carbamate condenser is not effected completely. Remaining gases are condensed in the reactor and provide the heat required for the dehydration of carbamate, as well as for heating the mixture to its equilibrium temperature. In an improvement to this process, the condensation of off-gas from the stripper is carried out in a prereactor, where sufficient residence time for the liquid phase is provided. As a result of urea and water formation in the condensing zone, the condensation temperature is increased, thus enabling the production of steam at a higher pressure level [40].

The feed carbon dioxide, invariably originating from an associated ammonia plant, always contains hydrogen. To avoid the formation of explosive hydrogen – oxygen mixtures in the tail gas of the plant, hydrogen is catalytically removed from the carbon dioxide feed (b). Apart from the air required for this purpose, additional air is supplied to the fresh carbon dioxide input stream. This extra portion of oxygen is needed to maintain a corrosion-resistant layer on the stainless steel in the synthesis section. Before the inert gases, mainly oxygen and nitrogen, are purged from the synthesis section, they are washed with carbamate solution from the low-pressure recirculation stage in the high-pressure scrubber (f) to obtain a low ammonia concentration in the subsequently purged gas. Further washing of the off-gas is performed in a low-pressure absorber (g) to obtain a purge gas that is practically ammonia free. Only one low-pressure recirculation stage is required due to the low ammonia and carbon dioxide concentrations in the stripped urea solution. Because of the ideal ratio between ammonia and carbon dioxide in the recovered gases in this section, water dilution of the resultant ammonium carbamate is at a minimum despite the low pressure (about 4 bar). As a result of the efficiency of the stripper, the quantities of ammonium carbamate for recycle to the synthesis section are also minimized, and no separate ammonia recycle is required.

The urea solution coming from the recirculation stage contains about 75 wt % urea. This solution is concentrated in the evaporation section (k). If the process is combined with a prilling tower for final product shaping, the final moisture content of urea from the evaporation section is ca. 0.25 wt %. If the process is combined with a granulation unit, the final moisture content may vary from 1 to 5 wt %, depending on granulation requirements. Higher moisture contents can be realized in a single-stage evaporator, whereas low moisture contents are economically achieved in a two-stage evaporation section.

When urea with an extremely low biuret content is required (at a maximum of 0.3 wt %), pure urea crystals are produced in a crystallization section. These crystals are separated from the mother liquor by a combination of sieve bends and centrifuges and are melted prior to final shaping in a prilling tower or granulation unit.

The process condensate emanating from water evaporation from the evaporation or crystallization sections contains ammonia and urea. Before this process condensate is purged, urea is hydrolyzed into ammonia and carbon dioxide (l), which are stripped off with steam and returned to urea synthesis via the recirculation section. This process condensate treatment section can produce water with high purity, thus transforming this "wastewater" treatment into the production unit of a valuable process condensate, suitable for, e.g., cooling tower or boiler feedwater makeup. Since the introduction of the Stamicarbon CO_2-stripping process, some 125 units have been built according to this process all over the world.

Figure 19. Functional block diagram of the Snamprogetti self-stripping process

3.3.2.2. Snamprogetti Ammonia- and Self-Stripping Processes [41–47]

In the first generation of NH_3- and self-stripping processes, ammonia was used as stripping agent. Because of the extreme solubility of ammonia in the urea-containing synthesis fluid, the stripper effluent contained rather large amounts of dissolved ammonia, causing an ammonia overload in downstream sections of the plant. Later versions of the process abandoned the idea of using ammonia as stripping agent; stripping was achieved only by supply of heat ("thermal" or "self"-stripping). Even without using ammonia as a stripping agent, the $NH_3 : CO_2$ ratio in the stripper effluent is relatively high, so the recirculation section of the plant requires an ammonia – carbamate separation section, as in conventional processes (see Fig. 19).

The process uses a vertical layout in the synthesis section. Recycle within the synthesis section, from the stripper (h) via the high-pressure carbamate condenser (f), through the carbamate separator (e) back to the reactor (b), is maintained by using an ammonia-driven liquid – liquid ejector (c) [43], [45] (see Fig. 20). In the reactor, which is operated at 150 bar, an $NH_3 : CO_2$ molar feed ratio of ca. 3.5 is applied. The stripper is of the falling film type [46]. Since stripping is achieved thermally, relatively high temperatures (200 – 210 °C) are required to obtain a reasonable stripping efficiency. Because of this high temperature, stainless steel is not suitable as construction material for the stripper from a corrosion point of view; titanium and bimetallic zirconium – stainless steel tubes have been used [37], [38].

Off-gas from the stripper is condensed in a kettle-type boiler (f) [44]. At the tube side of this condenser the off-gas is absorbed in recycled liquid carbamate from the medium-pressure recovery section. The heat of absorption is removed through the tubes, which are cooled by the production of low-pressure steam at the shell side. The steam produced is used effectively in the back end of the process.

In the medium-pressure decomposition and recirculation section, typically operated at 18 bar, the urea solution from the high-pressure stripper is subjected to the decomposition of carbamate and evaporation of ammonia (i). The off-gas from this medium-pressure decomposer is rectified. Liquid ammonia reflux is applied to the top of this rectifier (j); in this way a top product consisting of pure gaseous ammonia, and a bottom product of liquid ammonium carbamate are obtained. The pure ammonia off-gas is condensed (k) and recycled to the urea synthesis section. To prevent solidification of ammonium carbamate in the rectifier, some water is added to the bottom section of the column to dilute the ammonium carbamate below its crystallization point. The liquid ammonium carbamate – water mixture obtained in this way is also recycled to

the synthesis section. The purge gas of the ammonia condensers is treated in a scrubber (n) prior to being purged to the atmosphere.

The urea solution from the medium-pressure decomposer is subjected to a second lowpressure decomposition step (o). Here, further decomposition of ammonium carbamate is achieved, so that a substantially carbamate-free aqueous urea solution is obtained. Off-gas from this low-pressure decomposer is condensed (p) and recycled as an aqueous ammonium carbamate solution to the synthesis section via the medium-pressure recovery section.

Concentrating the urea – water mixture obtained from the low-pressure decomposer is performed in a single or double evaporator (s – v), depending on the requirements of the finishing section. Typically, if prilling is chosen as the final shaping procedure, a two-stage evaporator is required, whereas in the case of a fluidized-bed granulator a single evaporation step is sufficient to achieve the required final moisture content of the urea melt. In some versions of the process, heat exchange is applied between the off-gas from the medium-pressure decomposer and the aqueous urea solution to the evaporation section. In this way, the consumption of low-pressure steam by the process is reduced.

The process condensate obtained from the evaporation section is subjected to a desorption – hydrolysis operation to recover the urea and ammonia contained in the process condensate.

Up to now, about 70 plants have been designed according to the Snamprogetti ammonia- and self-stripping processes.

3.3.2.3. ACES Process [29], [48], [49]

The ACES (i.e., Advanced Process for Cost and Energy Saving) process has been developed by Toyo Engineering Corporation. Its synthesis section consists of the reactor (a), stripper (d), two parallel carbamate condensers (e), and a scrubber (f) – all operated at 175 bar (see Figs. 21 and 22).

The reactor is operated at 190 °C and an NH_3 : CO_2 molar feed ratio of 4 : 1. Liquid ammonia is fed directly to the reactor, whereas gaseous carbon dioxide after compression is introduced into the bottom of the stripper as a stripping aid. The synthesis mixture from the reactor, consisting of urea, unconverted ammonium carbamate, excess ammonia, and water, is fed to the top of the stripper. The stripper has two functions. Its upper part is equipped with trays where excess ammonia is partly separated from the stripper feed by direct countercurrent contact of the feed solution with the gas coming from the lower part of the stripper. This prestripping in the top is said to be required to achieve effective CO_2 stripping in the lower part. In the lower part of the stripper (a falling film heater), ammonium carbamate is decomposed and the resulting CO_2 and NH_3 as well as the excess NH_3 are evaporated by CO_2 stripping and steam heating. The overhead gaseous mixture from the top of the stripper is introduced into the carbamate condensers (e). Here, two units in parallel are installed, where the gaseous mixture is condensed and absorbed by the carbamate solution coming from the medium-pressure recovery stage. Heat liberated in the high-pressure carbamate condensers is used to generate low-pressure steam in one of the condensers and to heat the urea solution from the stripper after the pressure is reduced to about 19 bar in the shellside of the second carbamate condenser. The gas and liquid from the carbamate condensers are recycled to the reactor by gravity flow. The urea solution from the stripper, with a typical NH_3 content of 12 wt %, is purified further in the subsequent
